ISO 17475:2005 Corrosion of metals and alloys – Electrochemical test methods – Guidelines for conducting potentiostatic and potentiodynamic polarization measurements

ISO 17864:2005 Corrosion of metals and alloys – Determination of the critical pitting temperature under potentiostatic control

ISO 21207:2004 Corrosion tests in artificial atmospheres – Accelerated corrosion tests involving alternate exposure to corrosion-promoting gases, neutral salt-spray and drying

ISO 21610:2009 Corrosion of metals and alloys – Accelerated corrosion test for intergranular corrosion susceptibility of austenitic stainless steels.

## B. 2 IEC Standards

IEC standards are produced by the International Electrotechnical Commission. They use a naming convention similar to ISO.

IEC 60068-2-11: Edition 3, 1981: Environmental testing – Part 2: Tests. Test – Ka: Salt mist

IEC 60068-2-42: Edition 3, 2003: Environmental testing – Part 2-42: Tests – Test Kc: Sulfur dioxide test for contacts and connections

IEC 60068-2-43: Edition 2, 2003: Environmental testing – Part 2-43: Tests – Test Kd: Hydrogen sulfide test for contacts and connections

IEC 60068-2-46: Edition 1, 1982 Environmental testing – Part 2: Tests. Guidance to Test – Kd: Hydrogen sulfide test for contacts and connections

IEC 60068-2-60: Edition 2, 1995: Environmental testing – Part 2: Tests – Test Ke: Flowing mixed gas corrosion test

IEC 60068-2-49: Edition 1, 1983: Environmental testing – Part 2: Tests. Guidance to Test – Kc: Sulfur dioxide test for contacts and connections

IEC 60068-2-52: Edition 2, 1996: Environmental testing – Part 2: Tests – Test Kb: Salt mist, cyclic (sodium chloride solution).

## B. 3 ASTM Standards

ASTM standards use names of the form Xnnn-yy (yyyy), where X is a letter that indicates the general area of the standard (most corrosion standards start with G), nnn is the standard number, yy is the last two digits of the year in which the standard was last revised and yyyy (if present) is the year in which the standard was last reapproved. In the main text we have given only the standard letter and number; here we list the version of the standard that is current at the time of writing (May 2009).

A262-02a (2008) Standard Practices for detecting susceptibility to intergranular attack in austenitic stainless steels

A380-06 Standard Practice for Cleaning, Descaling, and Passivation of Stainless Steel Parts, Equipment, and Systems

A763-93(2009) Standard practices for detecting susceptibility to intergranular attack in ferritic stainless steels

B117-07a Standard practice for operating salt-spray (fog) apparatus

B154-05 Standard test method for mercurous nitrate test for copper alloys

B368–97(2003)e1 Standard method for copper-accelerated acetic acid-salt-spray (fog) testing (CASS test)

B380–97(2008)e1 Standard test method for corrosion testing of decorative electrodeposited coatings by the Corrodikote procedure

B457–67(2008)e1 Standard test method for measurement of impedance of anodic coatings on aluminum.

B537–70(2007) Standard practice for rating of electroplated panels subjected to atmospheric exposure

B735–06 Standard test method for porosity in gold coatings on metal substrates by nitric acid vapor

D130–04e1 Standard test method for corrosiveness to copper from petroleum products by copper strip test

D610–08 Standard practice for evaluating degree of rusting on painted steel surfaces

D714–02e1 Standard test method for evaluating degree of blistering of paints

D807–05 Standard practice for assessing the tendency of industrial boiler waters to cause embrittlement (USBM Embrittlement Detector Method)

D849–05 Standard test method for copper strip corrosion by industrial aromatic hydrocarbons

D1014–09 Standard practice for conducting exterior exposure tests of paints and coatings on metal substrates

D1280–00(2007) Standard guide for total immersion corrosion test for soak tank metal cleaners

D1384–00(2005) Standard test method for corrosion produced by leather in contact with metal

D1654–08 Standard test method for evaluation of painted or coated specimens subjected to corrosive environments

D1743–05ae1 Standard test method for determining corrosion preventive properties of lubricating greases

D1748–02(2008) Standard test method for rust protection by metal preservatives in the humidity cabinet

D1838–07 Standard test method for copper strip corrosion by liquefied petroleum (LP) gases

D2059–03 Standard test method for resistance of zippers to salt spray (fog)

D2247–02 Standard practice for testing water resistance of coatings in 100% relative humidity

D2251–96(2004) Standard test method for metal corrosion by halogenated organic solvents and their admixtures

D2570–08 Standard test method for simulated service corrosion testing of engine coolants

D2688–05 Standard test methods for corrosivity of water in the absence of heat transfer (weight loss methods)

D2758–94(2003) Standard test method for engine coolants by engine dynamometer

D2803–03 Standard guide for testing filiform corrosion resistance of organic coatings on metal

D2809–04e2 Standard test method for cavitation corrosion and erosion-corrosion characteristics of aluminum pumps with engine coolants

D2847–07 Standard practice for testing engine coolants in car and light truck service

D2943–02(2007) Standard test method for aluminum scratch of 1,1,1-trichloroethane to determine stability

D3310–00(2006) Standard test method for determining corrosivity of adhesive materials

D3843–00(2008) Standard practice for quality assurance for protective coatings applied to nuclear facilities

D3911–08 Standard test method for evaluating coatings used in light-water nuclear power plants at simulated design basis accident (DBA) conditions

D3912–95(2001) Standard test method for chemical resistance of coatings used in light-water nuclear power plants

D3929–03 Standard test method for evaluating stress cracking of plastics by adhesives using the bent-beam method

D4340–96(2007) Standard test method for corrosion of cast aluminum alloys in engine coolants under heat-rejecting conditions

D4350–00(2005) Standard test method for corrosivity index of plastics and fillers

D4627–92(2007) Standard test method for iron chip corrosion for water-dilutable metalworking fluids

D4798–08 Standard practice for accelerated weathering test conditions and procedures for bituminous materials (Xenon-Arc method)

D5144–08 Standard guide for use of protective coating standards in nuclear power plants

E647–08 Standard test method for measurement of fatigue crack growth rates

F363–99(2004) Standard test method for corrosion testing of gaskets

F482–03 Standard test method for corrosion of aircraft metals by total immersion in maintenance chemicals

F483–08 Standard test method for total immersion corrosion test for aircraft maintenance chemicals

F981–04 Standard practice for assessment of compatibility of biomaterials for surgical implants with respect to effect of materials on muscle and bone  
F1110–08 Standard test method for sandwich corrosion test

G1–03 Standard practice for preparing, cleaning, and evaluating corrosion test specimens

G2/G2M–06 Standard test method for corrosion testing of products of zirconium, hafnium, and their alloys in water at 680°F [360°C] or in steam at 750°F [400°C]

G3–89 (2004) Standard practice for conventions applicable to electrochemical measurements in corrosion testing

G4–01 (2008) Standard guide for conducting corrosion tests in field applications

G5–94 (2004) Standard reference test method for making potentiostatic and potentiodynamic anodic polarization measurements

G7–05 Standard practice for atmospheric environmental exposure testing of nonmetallic materials

G11–04 Standard test method for effects of outdoor weathering on pipeline coatings

G15–08 Standard terminology relating to corrosion and corrosion testing

G16–95 (2004) Standard guide for applying statistics to analysis of corrosion data

G28–02 (2008) Standard test methods for detecting susceptibility to intergranular corrosion in wrought nickel-rich, chromium-bearing alloys

G30–97 (2003) Standard practice for making and using U-bend stress corrosion test specimens

G31–72 (2004) Standard practice for laboratory immersion corrosion testing of metals

G32–06 Standard test method for cavitation erosion using vibratory apparatus

G33–99 (2004) Standard practice for recording data from atmospheric corrosion tests of metallic-coated steel specimens

G34–01 (2007) Standard test method for exfoliation corrosion susceptibility in 2XXX and 7XXX series aluminum alloys (EXCO test)

G35–98 (2004) Standard practice for determining the susceptibility of stainless steels and related nickel–chromium–iron alloys to stress corrosion cracking in polythionic acids

G36–94 (2006) Standard practice for evaluating stress corrosion cracking resistance of metals and alloys in a boiling magnesium chloride solution

G37–98 (2004) Standard practice for use of Mattson's solution of pH 7.2 to evaluate the stress corrosion cracking susceptibility of copper–zinc alloys

G38–01 (2007) Standard practice for making and using C-ring stress corrosion test specimens

G39–99 (2005) Standard practice for preparation and use of bent-beam stress corrosion test specimens

G41–90 (2006) Standard practice for determining cracking susceptibility of metals exposed under stress to a hot salt environment

G44–99 (2005) Standard practice for exposure of metals and alloys by alternate immersion in neutral 3.5% sodium chloride solution

G46–94 (2005) Standard guide for examination and evaluation of pitting corrosion

G47–98 (2004) Standard test method for determining susceptibility to stress corrosion cracking of 2XXX and 7XXX aluminum alloy products

G48–03 Standard test method for pitting and crevice corrosion resistance of stainless steels and related alloys by the use of ferric chloride solution

G49–85 (2005) Standard practice for preparation and use of direct tension stress corrosion test specimens

G50–76 (2003) Standard practice for conducting atmospheric stress corrosion tests on metals

G51–95 (2005) Standard test method for measuring pH of soil for use in corrosion testing

G52–00 (2006) Standard practice for exposing and evaluating metals and alloys in surface seawater

G57–06 Standard test method for field measurement of soil resistivity using the Wenner four-electrode method

G58–85 (2005) Standard practice for the preparation of stress corrosion test specimen for weldments

G59–97 (2003) Standard test method for conducting potentiodynamic polarization resistance measurements

G60–01 (2007) Standard practice for conducting cyclic humidity exposures

G61–86 (2003)e1 Standard test method for conducting cyclic potentiodynamic polarization measurements for localized corrosion susceptibility of iron-, nickel-, or cobalt-based alloys

G64–99 (2005) Standard classification of resistance to stress corrosion cracking of heat treatable aluminum alloys

G66–99 (2005)e1 Standard test method for visual assessment of exfoliation corrosion susceptibility of 5XXX series aluminum alloys (ASSET test)

G67–04 Standard test method for determining the susceptibility to intergranular corrosion of 5XXX series aluminum alloys by mass loss after exposure to nitric acid (NAMLT test)

- G69–97 (2003) Standard test method for measurement of corrosion potentials of aluminum alloys
- G71–81 (2003) Standard guide for conducting and evaluating galvanic corrosion tests in electrolytes
- G 73–04 Standard practice for liquid impingement erosion testing
- G78–01 (2007) Standard guide for crevice corrosion testing of iron base and nickel base stainless steels in seawater and other chloride-containing aqueous environments
- G82–98 (2003) Standard guide for development and use of a galvanic series for predicting galvanic corrosion performance
- G84–89 (2005) Standard practice for measurement of time-of-wetness on surfaces exposed to wetting conditions as in atmospheric corrosion testing
- G85–02e1 Standard practice for modified salt spray (fog) testing
- G87–02 (2007) Standard practice for conducting moist SO<sub>2</sub> test
- G90–05 Standard practice for performing accelerated outdoor weathering of nonmetallic materials using concentrated natural sunlight
- G91–97 (2004) Standard practice for monitoring atmospheric SO<sub>2</sub> using sulfation plate technique
- G92–86 (2003) Standard practice for characterization of atmospheric test sites
- G96–90(2008) Standard guide for online monitoring of corrosion in plant equipment (electrical and electrochemical methods)
- G97–97(2007) Standard test method for laboratory evaluation of magnesium sacrificial anode test specimens for underground applications
- G100–89(2004) Standard test method for conducting cyclic galvanostaircase polarization
- G101–04 Standard guide for estimating the atmospheric corrosion resistance of low-alloy steels
- G102–89 (2004)e1 Standard practice for calculation of corrosion rates and related information from electrochemical measurements
- G103–97 (2005) Standard practice for evaluating stress-corrosion cracking resistance of low copper 7XXX series Al-Zn-Mg-Cu alloys in boiling 6% sodium chloride solution
- G104:1989 Test method for assessing galvanic corrosion caused by the atmosphere
- G106–89(2004) Standard practice for verification of algorithm and equipment for electrochemical impedance measurements
- G107–95(2008) Standard guide for formats for collection and compilation of corrosion data for metals for computerized database input
- G108–94(2004)e1 Standard test method for electrochemical reactivation (epr) for detecting sensitization of AISI type 304 and 304L stainless steels
- G109–07 Standard test method for determining effects of chemical admixtures on corrosion of embedded steel reinforcement in concrete exposed to chloride environments
- G110–92(2003)e1 Standard practice for evaluating intergranular corrosion resistance of heat treatable aluminum alloys by immersion in sodium chloride + hydrogen peroxide solution
- G111–97(2006) Standard guide for corrosion tests in high temperature or high pressure environment, or both
- G112–92(2003) Standard guide for conducting exfoliation corrosion tests in aluminum alloys
- G116–99(2004) Standard practice for conducting wire-on-bolt test for atmospheric galvanic corrosion
- G123–00(2005) Standard test method for evaluating stress-corrosion cracking of stainless alloys with different nickel content in boiling acidified sodium chloride solution
- G129–00(2006) Standard practice for slow strain rate testing to evaluate the susceptibility of metallic materials to environmentally assisted cracking
- G135–95(2007) Standard guide for computerized exchange of corrosion data for metals
- G139–05 Standard Test method for determining stress-corrosion cracking resistance of heat-treatable aluminum alloy products using breaking load method
- G140–02(2008) Standard test method for determining atmospheric chloride deposition rate by wet candle method
- G142–98(2004) Standard test method for determination of susceptibility of metals to embrittlement in hydrogen containing environments at high pressure, high temperature, or both
- G146–01(2007) Standard practice for evaluation of disbonding of bimetallic stainless alloy/steel plate for use in high-pressure, high temperature refinery hydrogen service
- G148–97(2003) Standard practice for evaluation of hydrogen uptake, permeation, and transport in metals by an electrochemical technique
- G150–99(2004) Standard test method for electrochemical critical pitting temperature testing of stainless steels
- G152–06 Standard practice for operating open flame carbon arc light apparatus for exposure of nonmetallic materials

G153–04 Standard practice for operating enclosed carbon arc light apparatus for exposure of nonmetallic materials

G157–98(2005) Standard guide for evaluating the corrosion properties of wrought iron- and nickel-based corrosion resistant alloys for the chemical process industries

G158–98(2004) Standard guide for three methods of assessing buried steel tanks

G162–99(2004) Standard practice for conducting and evaluating laboratory corrosion tests in soils

G165–99(2005) Standard practice for determining rail-to-earth resistance

G168–00(2006) Standard practice for making and using precracked double beam stress corrosion specimens

G170–06 Standard guide for evaluating and qualifying oilfield and refinery corrosion inhibitors in the laboratory

G180–07 Standard test method for initial screening of corrosion inhibiting admixtures for steel in concrete

G184–06 Standard practice for evaluating and qualifying oil field and refinery corrosion inhibitors using rotating cage

G185–06 Standard practice for evaluating and qualifying oil field and refinery corrosion inhibitors using the rotating cylinder electrode

G186–05 Standard test method for determining whether gas-leak-detector fluid solutions can cause stress corrosion cracking of brass alloys

G187–05 Standard test method for measurement of soil resistivity using the two-electrode soil box method

G188–05 Standard specification for leak detector solutions intended for use on brasses and other copper alloys

G189–07 Standard guide for laboratory simulation of corrosion under insulation

G192–08 Standard test method for determining the crevice repassivation potential of corrosion-resistant alloys using a potentiodynamic-galvanostatic-potentiostatic technique.

## B. 4 NACE Standards

NACE standards are produced by NACE International (formerly the National Association of Corrosion Engineers). They use the naming convention NACE XXnnnn-yyyy, where XX is the type of

standard, nnnn the standard number and yyyy the year of publication. Here we list only the TM (Test Method) standards; the full list can be found on the NACE website ([www.nace.org](http://www.nace.org)).

TM0101–2001 Measurement techniques related to criteria for cathodic protection on underground or submerged metallic tank systems

TM0102–2002 Measurement of protective coating electrical conductance on underground pipelines

TM0103–2003 Laboratory test procedures for evaluation of SOHIC resistance of plate steels used in wet H<sub>2</sub>S service

TM0104–2004 Offshore platform ballast water tank coating system evaluation

TM0105–2005 Test procedures for organic-based conductive coating anodes for use on concrete structures

TM0106–2006 Detection, testing, and evaluation of microbiologically influenced corrosion (MIC) on external surfaces of buried pipelines

TM0108–2008 Testing of catalyzed titanium anodes for use in soils or natural waters

TM0109–2009 Above ground survey techniques for the evaluation of underground pipeline coating condition

TM0169–2000 Laboratory corrosion testing of metals

TM0172–2001 Determining corrosive properties of cargoes in petroleum product pipelines

TM0173–2005 Methods for determining quality of subsurface injection water using membrane filters

TM0174–2002 Laboratory methods for the evaluation of protective coatings and lining materials on metallic substrates in immersion service

TM0177–2005 Laboratory testing of metals for resistance to sulfide stress cracking and stress corrosion cracking in H<sub>2</sub>S environments

TM0183–2006 Evaluation of internal plastic coatings for corrosion control of tubular goods in an aqueous flowing environment

TM0185–2006 Evaluation of internal plastic coatings for corrosion control of tubular goods by autoclave testing

TM0186–2002 Holiday detection of internal tubular coatings of 250- to 760- $\mu$ m (10 to 30 mils) dry-film thickness

TM0187–2003 Evaluating elastomeric materials in sour gas environments

TM0190–2006 Impressed current laboratory testing of aluminum alloy anodes

TM0192–2003 Evaluating elastomeric materials in carbon dioxide decompression environments

TM0193–2000 Laboratory corrosion testing of metals in static chemical cleaning solutions at temperatures below 93°C (200°F)

TM0194–2004 Field monitoring of bacterial growth in oil and gas systems

TM0197–2002 Laboratory screening test to determine the ability of scale inhibitors to prevent the precipitation of barium sulfate and/or strontium sulfate from solution (for oil and gas production systems)

TM0198–2004 Slow strain-rate test method for screening corrosion-resistant alloys (CRAs) for stress corrosion cracking in sour oilfield service

TM0199–2006 Standard test method for measuring deposit mass loading (deposit weight density) values for boiler tubes by the glass-bead-blasting technique

TM0204–2004 Exterior protective coatings for seawater immersion service

TM0208–2008 Laboratory test to evaluate the vapor-inhibiting ability of volatile corrosion inhibitor materials for temporary protection of ferrous metal surfaces

TM0284–2003 Evaluation of pipeline and pressure vessel steels for resistance to hydrogen-induced cracking

TM0286–2001 Cooling water test unit incorporating heat transfer surfaces

TM0294–2007 Testing of embeddable impressed current anodes for use in cathodic protection of atmospherically exposed steel-reinforced concrete

TM0296–2002 Evaluating elastomeric materials in sour liquid environments

TM0297–2008 Effects of high temperature, high-pressure carbon dioxide decompression on elastomeric materials

TM0298–2003 Evaluating the compatibility of FRP pipe and tubulars with oilfield environments

TM0304–2004 Offshore platform atmospheric and splash zone maintenance coating system evaluation

TM0374–2007 Laboratory screening tests to determine the ability of scale inhibitors to prevent the precipitation of calcium sulfate and calcium carbonate from solution (for oil and gas production systems)

TM0384–2002 Holiday detection of internal tubular coatings of less than 250- $\mu\text{m}$  (10 mils) dry-film thickness

TM0397–2002 Screening tests for evaluating the effectiveness of gypsum scale removers

TM0399–2005 Standard test method for phosphonate in brine

TM0404–2004 Offshore platform atmospheric and splash-zone new construction coating system evaluation

TM0497–2002 Measurement techniques related to criteria for cathodic protection on underground or submerged metallic piping systems

TM0498–2006 Evaluation of the carburization of alloy tubes used for ethylene manufacture

TM0499–99 Immersion corrosion testing of ceramic materials.

## B. 5 Other National Standards

Most other national standards have been subsumed into ISO standards. Thus, the British Standards Institute (BSI) now markets standards as BS EN ISO xxxx (for British Standard, European Norm, ISO xxxx).

### Symbols

**$E$**  Modulus of elasticity

**$E_{\text{corr}}$**  Corrosion potential

**$h$**  Height

**$I$**  Current density

**$K_{\text{ISCC}}$**  Threshold stress intensity factor for the onset  
of stress corrosion cracking

**$t$**  Specimen thickness

**$t_f$**  Time to failure

**$V$**  Potential

**$\sigma$**  Maximum tensile stress

**$\sigma_{\text{th}}$**  Threshold stress for the onset of stress  
corrosion cracking

**$\sigma_y$**  Lower yield strength

### 2.35.1 Introduction

#### 2.35.1.1 Stressing Systems

Many different methods<sup>1–4</sup> have been used for the stressing of specimens (or testpieces), from which it may be reasonably assumed that there is no single method that is markedly superior to all the others. Each method may have its peculiar advantages in a given situation, but ideally, a test method should not be so severe that it leads to the condemnation of a material that would prove adequate for service or so trifling as to permit the use of materials in circumstances where rapid failure ensues. Methods of stressing testpieces, whether initially plain, notched, or precracked, can be conveniently grouped according to whether they involve:

1. a constant total strain or deflection;
2. a constant load;
3. an imposed strain or deflection rate.

Constant deflection tests usually have the attraction of employing simple and, therefore, often cheap

specimens and straining frames and of simulating the fabrication stresses that are most frequently associated with stress corrosion failure. Constant load tests may simulate failure from applied or working stresses more closely. Although tests involving the application of a constant deflection rate (strain rate) are commonly used, their relevance to service failures continues to be debated.

### 2.35.1.2 Constant Total-Deflection Tests

Prismatic beams stressed by bending offer a simple means of testing sheet or plate material, typical arrangements being shown in Figure 1(a)–1(e). Below the elastic limit, the stresses may be calculated<sup>1,5</sup> or

determined from the response of strain gauges attached to the surface at an appropriate position.

Plastic bending of strip specimens to produce a ‘U’-bend, Figure 1(d) and 1(e), will usually allow the use of a lighter restraining system, although some of the effects of the plastic deformation, if not removed by subsequent heat treatment, may be to influence cracking response, and the stress obtained in the outer fibers of the specimen is usually less reproducible than with more sophisticated specimens. Tubular material may be tested in the form of ‘C’- or ‘O’-rings, the former being stressed by partial closing of the gap, Figure 1(c), and the latter by the forced insertion of a plug that is appropriately oversized for the bore. The circumferential stress at the outer

**Figure 1** Stressing systems for stress corrosion test specimens; (a) to (f) constant strain, (g) constant load.

surface of a 'C'-ring is maximal midway between the bolt holes, but for the 'O'-ring, it is constant over the periphery, the stresses being readily calculated in terms of measured deflections.<sup>1,2</sup>

Constant-deflection tensile tests, **Figures 1(f) and 1(g)**, are sometimes preferred to bend tests, but for similar cross sections, require a more massive restraining frame. In principle, this problem may be surmounted by the use of internally stressed specimens containing residual stresses as the result of inhomogeneous deformation. The latter may be introduced by plastic bending, for example, by producing a bulge in sheet or plate material, or by welding, but such tests cause problems in the systematic variation of the initial stress, which will usually be in the region of the yield stress. Moreover, elastic spring-back, in introducing residual stresses by bulging plate or partially flattening tube, may introduce problems, and where welding is involved, the structural modifications may raise difficulties unless the test is simulative of a practical situation.

At least as important as the choice of methods of stressing is the realization of the limitations of the various methods, these having been considered in a review of stress corrosion test methods.<sup>6</sup> The stiffness of the stressing frame in constant-deflection tests may influence results because of relaxation in the specimen during the initial loading stage and during subsequent crack propagation. Especially in testing ductile materials, the initial elastic strain is converted in part to plastic strain, even if the total deflection remains constant during cracking. This is because, as the crack propagates, the stress increases on the remaining uncracked portion of the specimen section beyond the crack, eventually reaching the effective yield stress. Yielding will then occur, accompanied by yawning of the crack and frequently, with the propagation of a Lüders band that results in a sharp load drop, which is sometimes mistaken as an indication of the crack having advanced by a burst of mechanical fracture. Once load relaxation has been initiated, the extent to which it proceeds can vary from specimen to specimen. Thus, **Figure 2** shows load relaxation curves for two specimens of the same maraging steel in the same stressing frame, which had a facility for load recording throughout the test. The specimens differed in the extent to which they showed load relaxation prior to sudden fracture, this difference being related to the number of cracks that developed in the specimens. Marked load relaxation was associated with the development of many cracks in the specimen and little relaxation, with only a few cracks.

**Figure 2** Load relaxation curves for a maraging steel stress corroded in 0.6 M NaCl at pH 2. Reproduced from Parkins, R. N.; Haney, E. G. *Trans. Metall. Soc., AIME* **1968**, 242, 1943.

This can influence the time to failure, as is apparent from **Figure 2**, where the specimen stressed at the initially higher load took longer to fail than that at the initially lower one. This is because, when only a single stress corrosion crack develops, it will not need to grow to large dimensions before sudden, final failure occurs, since the applied load remains high, whereas with the marked load relaxation associated with the multicroaked specimen, one of the cracks will need to propagate much further before it reaches the size for sudden fracture at the reduced load. Such an explanation conforms to the observations<sup>7</sup> that the load at fracture is related to the area of stress corrosion cracking upon the final fracture surface and to the number of cracks initiated.

This type of result will depend upon the nature of the stress corrosion system being studied, that is, upon such properties as the fracture toughness of the material and even upon the aggressiveness of the environment employed. It will also vary according to the stiffness of the restraining jig employed, since the stiffer the frame, the less the elastic strain that is likely to remain in the specimen after the propagation of a Lüders band, so that a stress-corrosion crack may cease to propagate in some circumstances, especially if the initial stress is in the vicinity of the threshold stress. This indicates some of the dangers inherent in comparing stress corrosion resistances in terms of times to failure at a given initial stress, an approach that is often practiced but can be misleading. **Figure 3** shows the results from some tests in which the time to failure of specimens previously cold worked in varying amounts is plotted against initial stress. Comparison of the effects of different amounts of cold work by tests at an initial

**Figure 3** Effects of different amounts of prior cold work (0, 10 and 34%) on the stress corrosion of a 0.07% C steel in boiling 4 M  $\text{NH}_4\text{NO}_3$ .

**Table 1** Relative susceptibilities to cracking of a mild steel in boiling 4 M  $\text{NH}_4\text{NO}_3$  after various amounts of cold work

Initial stress	Susceptibility of different cold-worked conditions		
	Most (%)	Intermediate (%)	Least (%)
280 MPa	0	10	34
155 MPa	10	34	0
100% of yield stress	34	10	0
30% of yield stress	10	34	0

stress of 280 or 155 MPa gives different orders of susceptibility, as shown in **Table 1**. It could be argued that neither of these results is correct because the prior cold work would result in different yield strengths being developed in the three different conditions and that the results should be rationalized by making the comparison a function of the respective yield strengths. Here again, however, the order of susceptibility varies according to the rationalized stress at which the comparison is made, as the results in **Table 1** show. It is difficult to escape the conclusion that a more satisfactory basis of comparison is the threshold, but even the latter may not be a basis for comparison of results obtained using different restraining frames.

The simplicity of the rigs used in the constant-strain tests is an advantage in the application of the corrosive solution. Thus, in the case of two-point bending, **Figure 1(a)**, several specimens may be strained in the same rig, which can be constructed of plastic and immersed in a tank containing the test solution.

### 2.35.1.3 Constant-Load Tests

Dead-weight loading (with or without the assistance of levers to reduce the load requirements) of tensile specimens has the advantage of avoiding some of the difficulties already discussed, not the least in allowing accurate determination of the stress if the specimen is uniaxially loaded. The relatively massive machinery usually required for such tests upon specimens of appreciable cross section is sometimes circumvented by the use of a compression spring, **Figure 1(g)**, chosen with characteristics that ensure that it does not change significantly in length during testing, thereby approximating to a constant-load application. For immersion tests, the frame may be coated in polymer and the specimen insulated from the shackles by plastic sleeves and washers to avoid bimetallic effects; alternatively, the specimen may be enclosed in a glass cell containing the test solution. The alternative approach of minimizing the size of the loading system by reducing the cross section of the specimen to the dimensions of a wire is dangerous unless failure by stress corrosion cracking is confirmed by, say, metallography. This is because failure may result from pitting and an attendant increase in the effective stress to the ultimate tensile strength (UTS) in some stress corrosion environments. Indeed, there is evidence for some systems that before stress corrosion cracking proper can begin, a pit must form wherein certain chemical or electrochemical conditions are established that permit cracks to be initiated, and in such systems, the use of fine wires has obvious pitfalls.

The load relaxation that accompanies some, if not all, constant-deflection tests is replaced in constant-load tests by an increasing stress condition, since the effective cross section of the test piece is reduced by crack propagation. This suggests that it will be less likely that cracks will cease to propagate once initiated, as may happen with constant deflection tests at initial stresses in the region of the threshold stress, and therefore, the threshold stresses are likely to be lower when determined under constant-load conditions than under conditions of constant deflection. Some results attributed to Brenner and Gruhl<sup>8</sup> for an aluminum alloy, **Figure 4**, confirm this expectation. These results also show shorter times to failure for the same initial stress with constant load testing and, as already indicated for constant-deflection tests, raise queries as to the significance of time to failure, the parameter so frequently used in assessing cracking susceptibility.

**Figure 4** Comparison of test results from bend and tension tests upon Al-Zn-Mg alloy in 3% NaCl plus 0.1% H<sub>2</sub>O<sub>2</sub>. Reproduced from Brenner, P.; Gruhl, W. Z. *Metall.* **1961**, 52, 599.

#### 2.35.1.4 Slow Strain-Rate Tests

While this method of testing has been in use in some laboratories for two decades or more and has increased in use considerably in very recent years, there remain some skepticism and unfamiliarity with the method. In essence, it involves the application of a relatively slow strain or deflection rate ( $\sim 10^{-6} \text{ s}^{-1}$ ) to a specimen<sup>9</sup> subjected to appropriate electrochemical conditions. It should be emphasized that the strain rates employed are very much lower than those involved in straining electrode experiments where the object, the measurement of current transients, is totally different. In slow strain-rate corrosion tests, the object is to produce stress corrosion cracks that are metallographically indistinguishable from those produced in constant-load or constant-deflection experiments. The object in all these laboratory tests is normally to obtain data in a relatively shorter period of time, and this is frequently achieved by adopting an approach that increases the severity of the test. In stress corrosion testing, this usually takes the form of increasing the aggressiveness of the environment by changing its composition, temperature, or pressure, stimulating the corrosion reactions (galvanostatic or potentiostatic), increasing the susceptibility of the alloy through changes in structure, or increasing the severity of the stress by the introduction of a notch or precrack. The application of dynamic straining to a stress corrosion test specimen also comes into this last category, and, like all of the other accelerating approaches, its justification will vary according to the circumstances in which it is used.

Most stress corrosion crack velocities fall in the range from  $10^{-3}$  to  $10^{-6} \text{ mm s}^{-1}$ , which implies that failures in laboratory test specimens of usual dimensions occur in not more than a few days. This is found to be so if the system is one in which stress corrosion cracks are readily initiated, but it is common experience to find that some testpieces do not fail even after extended periods of testing, which are then terminated at some arbitrarily selected time. The consequences are that considerable scatter may be associated with replicate tests, and the arbitrary termination of the test leaves an element of doubt concerning what the outcome would have been if it had been allowed to continue for a longer time. Just as the use of precracked specimens assists in stress corrosion crack initiation, so does the application of slow dynamic strain, which has the further advantage that the test is not terminated after some arbitrary time, since the conclusion is always achieved by the specimen fracturing, and the criterion of cracking susceptibility is then related to the mode of fracture. Thus, in the form in which it is normally employed, the slow strain-rate method will result in failure in not more than  $\sim 2$  days, either by ductile fracture or by stress corrosion cracking, according to the susceptibility towards the latter, and metallographic or other parameters may then be assigned in assessing the cracking response. The fact that the test concludes in this positive manner in a relatively shorter period of time constitutes one of its main attractions.

Early use of the test was in providing data whereby the effects of such variables as alloy

composition and structure or inhibitive additions to cracking environments could be compared, and also for promoting stress corrosion cracking in combinations of alloy and environment that could not be caused to fail in the laboratory under conditions of constant load or constant strain. Thus, they constitute a relatively severe type of test in the sense that they frequently promote stress corrosion failure in the laboratory where other modes of stressing plain specimens do not promote cracking, and in this sense, they are in a category similar to tests on precracked specimens. In recent years, an understanding of the implications of dynamic strain testing has developed, and it now appears that this type of test may have much more relevance and significance than just that of an effective and rapid sorting test. It may, at first sight, be argued that laboratory tests involving the pulling of specimens to failure at a slow strain-rate show little relation to the reality of service failures. In point of fact, in constant-strain and constant-load tests, crack propagation also occurs under conditions of slow dynamic strain, to a greater or lesser extent depending upon the initial value of stress, the point in time during the test at which a stress corrosion crack is initiated, and various metallurgical parameters that govern creep in the specimen. Moreover, there is an increasing amount of evidence for some systems which suggests that the function of stress in stress corrosion cracking is to promote a strain rate which, rather than stress *per se*, is the parameter that really governs crack initiation or propagation. In these cases, the minimum creep rate for cracking is as much an engineering design parameter as is the threshold stress or stress-intensity factor obtained from constant-load tests on plain or precracked specimens.

The point may be illustrated by data for a ferritic steel exposed to a carbonate-bicarbonate solution as fatigue precracked cantilever beams subjected to constant loads. Deformation in the plastic zone associated with the precrack is time dependent following load applications and can be measured, and the threshold conditions for stress corrosion cracking defined, in terms of a limiting average creep rate over a specific time interval. That limiting creep rate may then be used in subsequent experiments to calculate the threshold stress from creep data determined independently, these calculated threshold stresses then being compared with values determined experimentally. The creep properties of ferritic steels may be varied by prior strain aging, following different amounts of cold work, and Figure 5 shows the observed and calculated threshold stresses from tests on specimens subjected to various strain aging treatments. Clearly,

**Figure 5** Observed and calculated values of the threshold net section stresses for stress corrosion cracking of a C-Mn steel after various prior deformations and aging treatments.

the general trend of the experimentally determined curve showing the effects of the amount of prior deformation is reflected in the calculated results.

The equipment required for slow strain-rate testing is simply a device that permits a selection of deflection rates while being powerful enough to cope with the loads generated. Plain or precracked specimens in tension may be used, but if the cross section of these needs to be large or the loads high for any reason, cantilever bend specimens with the beam deflected at appropriate rates may be used. It is important to appreciate that the same deflection rate does not produce the same response in all systems and that the rate has to be chosen in relation to the particular system studied.

The representation of the results from slow strain-rate tests may be through the usual ductility parameters, such as reduction in area, the maximum load achieved, the crack velocity, or even the time to failure, although as with all tests, metallographic or fractographic examination, while not readily quantifiable, should also be involved. Since stress corrosion failures are usually associated with relatively little

**Figure 6** Nominal stress–extension curves for mild steel in oil giving ductile failure, and in 4 M NaNO<sub>3</sub> producing stress corrosion failure, at the same test temperature (104 °C).

plastic deformation, the ductility of specimens will be variable according to the extent to which stress corrosion contributes to the fracture process. This will also influence the shape of the load–extension curve that may be obtained by continuous monitoring of the response of a load cell incorporated in the system; **Figure 6** shows the forms of curves obtained with and without attendant stress corrosion. It is apparent from these curves that not only is the extension to fracture dependent upon the presence or otherwise of stress corrosion cracks, but so also is the maximum load achieved. The latter may be used for expressing cracking susceptibility in some systems, as also may the area bounded by the load–extension curve. However, the variations in maximum load achieved in slow strain-rate tests in circumstances of varying cracking severity are not always large enough for significant distinctions to be made. Even measurements of ductility, such as reduction in area, are readily invariably not made, if only because the final fracture of the specimen does not always follow a simple path, and the fitting of the two broken pieces together is not easy. Probably, the easiest quantity to measure with reasonable accuracy is the time to failure, which has as much significance in a slow strain-rate test as it does in constant-load or constant-deflection tests. Indeed, the time to failure in slow strain-rate tests is simply related to ductility parameters, a not very surprising result when it is remembered that the less the intensity of stress corrosion cracking, the greater will be the ductility to fracture and therefore, the greater the time to failure for a given strain rate.

**Figure 7** Time to failure ratios from constant-deflection rate tests and normalized threshold stresses  $\sigma_{th}/\sigma_y$  obtained from constant-strain tests for a series of low-alloy ferritic steels in boiling 4 M NH<sub>4</sub>NO<sub>3</sub>.

Clearly, for slow strain-rate testing to have credence, it should give results that are comparable with those obtained by other methods. **Figure 7** shows some results for tests upon low-alloy ferritic steels in boiling 4 M NH<sub>4</sub>NO<sub>3</sub>, the various alloying elements producing a range of cracking susceptibilities as measured by the threshold stresses obtained from constant-strain tests. These results have been

normalized by dividing the threshold stress  $\sigma_{th}$  by the lower yield strength  $\sigma_y$  for each steel, while the slow strain test results have been normalized by dividing the time to failure in the 4 M  $NH_4NO_3$  by the time to failure in oil at the same temperature, so that increasing departure from unity indicates increasing cracking susceptibility. The general trend of the results in Figure 7 is clear in indicating reasonable agreement between the two types of tests in placing the steels in essentially the same order of merit.

Although slow strain-rate tests are most frequently taken to total failure in order to produce a 'go/no-go' type of result in which threshold stresses are not defined, they can be conducted in a manner that allows such definition. Specimens are preloaded to various initial stresses in the absence of the cracking environment or at a potential that prevents cracking, after which they are allowed to creep until the latter falls below the strain rate to be applied. The applied straining is continued for a sufficient time only to allow cracks to grow to a measurable size. During straining, the stress upon the specimen varies in a manner dependent upon the magnitude of the applied strain-rate, hence the importance of restricting the test time to no longer than that necessary to produce measurable cracks. The cracks are probably most conveniently measured by microscopy on longitudinal sections of the gauge lengths, the length of the deepest detectable crack divided by the test time giving an average crack velocity. Figure 8 shows some results from tests upon a cast nickel–aluminum bronze exposed to seawater<sup>10</sup> and clearly it is possible to define a threshold stress below which cracking is not observed. However, that threshold stress depends upon the strain-rate applied, as is to be expected. Another approach to defining threshold stresses in slow strain-rate tests that may sometimes be useful is to use tapered specimens, with the taper angle minimized to avoid complications by resolved components of the tensile load.<sup>11</sup> Applied to the cracking of  $\alpha$ -brass exposed to sodium nitrite solutions, a single tapered specimen gave threshold stresses close to those obtained by the use of a number of plain specimens loaded at a given strain rate to various stress levels.

## 2.35.2 Testpiece

### 2.35.2.1 Precracked Samples

The literature contains many references to the use of notched, as opposed to precracked or plain specimens

**Figure 8** Average stress corrosion crack velocity from monotonic slow strain rate tests at  $1.5 \times 10^{-7} \text{ s}^{-1}$  conducted over various restricted ranges of stress on a cast Ni–Al bronze in seawater at 0.15 V(SCE). The stress range traversed in each test is shown by the length of the bar. Reproduced from Parkins, R. N.; Suzuki, Y. *Corros. Sci.* **1983**, *23*, 577.

in laboratory studies of stress corrosion, for reasons of improved reproducibility, inability to crack plain specimens under otherwise identical conditions or ease of measuring some parameters, such as crack growth rate, when the crack location is predetermined. However, the developments in fracture mechanics have resulted in a whole new field of stress corrosion testing involving the use of specimens containing a sharp pre-crack, usually produced from a notch by subjecting the specimen to fatigue. The application of fracture mechanics to stress corrosion cracking is the subject of an admirable review by Brown,<sup>12</sup> and various aspects of the method are considered in papers presented at an Advisory Group for Aerospace Research and Development (AGARD) conference.<sup>13</sup>

The problems associated with the choice of plain specimens for assessing stress corrosion resistance may, at first sight, appear equally large in relation to pre-cracked specimens in the sense that in the relatively shorter time during which such tests have been in use, a large number of specimen types have been used (Figure 9). However, the differing specimen geometries are rationalized through the stress–intensity factor, with the result that data from different testpieces are comparable, provided appropriate precautions are taken in

**Figure 9** Classification of precracked specimens for stress corrosion testing. Reproduced from Smith, H. R.; Piper, D. E. Stress Corrosion Testing with Precracked Specimens, The Boeing Co, D6-24872, ARPA 878, June, 1970.

specimen preparation. The biggest single difficulty is in relation to the large size of specimen that is necessary for highly ductile materials if the concepts of linear elastic analysis are to be applicable. Since it is probable that most service stress corrosion failures occur in highly ductile materials in relatively thin sections, it is clear that there are problems here, but the use of precracked specimens that do not conform dimensionally to the requirements for linear elastic analysis to be strictly valid is still worthwhile in some instances, and in any case, developments in fracture mechanics over the last decade or so allow alternative approaches than that of linear elastic analysis.

Precracked specimens are sometimes useful for other reasons than the analysis that they afford in relation to stress-intensity factors. Such applications

may be associated with the simulation of service situations, the relative ease with which stress-corrosion cracks can be initiated at precracks, or the advantages that sometimes accrue from the propagation of a single crack. The claim that has sometimes been made of precracked specimen tests – that they circumvent the initiation stage of cracking in plain specimens, erroneously assumed invariably to be related to the creation of a corrosion pit that provides a measure of stress concentration approaching that achieved at the outset with a precrack – is rarely entirely valid. Thus, the geometries of a pit, notch, or precrack are often as important for electrochemical reasons as they are for any reason associated with their influences upon stress distribution. This is because a geometrical discontinuity may be necessary

to provide the localized electrochemical conditions, in terms of environment composition or electrode potential, that are necessary for stress corrosion crack propagation. The objections that have sometimes been made against the use of precracked specimens, for example, to the validity of introducing a transgranular precrack into a specimen that suffers intergranular stress corrosion cracking, or of the necessity of incurring a considerable expense to produce a very sharp crack when the introduction of a corrosive environment may blunt the crack by the dissolution, miss the point that such sharp discontinuities do indeed exist in some real materials. Indeed, one of the major attractions of precracked specimen testing is that it can provide data that allow the designation of the maximum allowable defect sizes in structures for the latter to remain in a safe condition.

In view of the significance of strain rate in stress corrosion cracking, mentioned earlier, it is good to remember that its significance is as applicable to precracked specimens as it is to initially plain specimens, in relevant systems. This has a number of implications, not the least of which is the possible influence of time delay between loading precracked specimens and exposing them to the test environment. Moreover, the limiting stress–intensity factor  $K_{ISCC}$ , above which cracks grow relatively rapidly (Figure 10) may well depend upon the conditions under which it is determined, and it should not be regarded as some property of the material equivalent to, say, a yield stress. There is now a considerable volume of data that shows how relatively small fluctuating stresses may reduce the threshold stresses or stress-intensity factors for stress corrosion cracking, and some of these effects are probably related to cyclic loading sustaining creep-related effects. Crack-tip strain rates have consequently become a topic of interest, and expressions are available for cyclically loaded precracked specimens<sup>14,15</sup> and also for multicracked specimens<sup>16</sup> of the form that initially plain specimens take during slow strain-rate tests.

### 2.35.2.2 Comparison of the Results from Plain and Precracked Specimens

It is clear that an initially plain specimen that develops a stress corrosion crack may, if the geometry is appropriate, conform to the conditions obtaining in an initially precracked specimen. This raises a question, despite the opposing views of the protagonists of the two types of testpieces, as to the comparability of the result from each. Figure 11 shows the results<sup>17</sup>

**Figure 10** Effect of applied stress intensity upon crack velocity for high-strength (1800 MPa UTS) quenched and tempered steel (AFC 77) in distilled water. Reproduced from Spiedel, M. O.; In Conference on *Hydrogen in Metals*; National Association of Corrosion Engineers, Houston, TX, 1975.

**Figure 11** Threshold stress intensities  $K_{ISCC}$  from precracked specimen tests, and threshold stresses  $\sigma_{th}$  from plain specimen tests, for a Mg–7Al alloy in various structural conditions tested in chromate–chloride solution. Reproduced from Wearmouth, W. R.; Dean, G. P.; Parkins, R. N. *Corrosion* **1973**, 29, 251.

obtained from stress corrosion tests upon a Mg–7Al alloy exposed to a chromate–chloride solution, the cracking susceptibility of the alloy being varied by different heat treatments. The implication of Figure 11 is that the threshold stress  $\sigma_{th}$ , determined upon initially plain specimens of small cross section, is related to the threshold stress intensity  $K_{ISCC}$  obtained from precracked specimens of relatively large section. Since  $K_{ISCC}$  represents the stress intensity below which an existing crack does not propagate, it would appear that the threshold stress given by tests on plain specimens corresponds to values below which cracks do not propagate to give total failure, that is, the threshold stress for plain specimens is not necessarily the stress below which cracks do not form. Examination of plain specimens stressed below the threshold stress revealed the presence of small stress corrosion cracks that had ceased to propagate and moreover, the maximum sizes of the cracks that did not propagate to total failure were quadratically related to the threshold stress, as would be expected if the concepts of fracture mechanics were applicable to these initially plain specimens. Nonpropagating cracks have also been observed at stresses below the threshold stress in other systems, such as low-alloy ferritic steels exposed to various environments, and would therefore, support the suggestion that what are being measured in tests upon plain and precracked specimens are not as different as has sometimes been suggested.

### 2.35.2.3 Crack Velocity Measurements

In mechanistic studies of stress corrosion and also in the collection of data for remaining-life predictions for plants there is need for stress corrosion crack velocity measurements to be made. In the simplest way, these can be made by microscopic measurements at the conclusion of tests, the assumption being that the velocity is constant throughout the period of exposure, or, if the crack is visible during the test, *in situ* measurements may be made by visual observation, the difficulty then being that it is assumed that the crack visible at a surface is representative of the behavior below the surface. Indirect measurements must frequently be resorted to, and these have involved observation of the elongation of the specimen, crack-opening displacement, changes in the electrical resistivity of the specimen, and acoustic emissions that sometimes accompany crack extension.

Measurement of the elongation of the specimen is probably the least satisfactory of all these, even though it is often the simplest, requiring a transducer

that responds to dimensional change. Multiple cracking of initially plain specimens raises problems in interpreting the data in terms of crack velocities, and so the technique has been frequently used for attempting to determine the point in time when cracking was initiated, the preceding time during which the transducer shows no response being equated to an incubation period for cracking. However, such results can be completely misleading because the sensitivity of most transducers is such that they will only detect change when the specimen undergoes some plastic deformation, resulting from the propagation of a crack to the size where the remaining uncracked portion of the section beyond the crack is raised to its yield strength. Consequently, crack propagation can occur during the (so-called) incubation period when the stress is insufficient to cause the propagation of a deformation band. The latter frequently occurs suddenly, producing a sharp response by the transducer, which has sometimes been interpreted as evidence of a burst of fast mechanical fracture but which may, in fact, be nothing of the sort. It is much more satisfactory to use a crack-opening displacement gauge<sup>18</sup> located across a precrack. These gauges usually take the form of two thin cantilever beams to which strain gauges are attached, the beams being located at opposite sides of the extremity of the precrack. As crack extension occurs and the sides of the crack undergo relative displacement, the strain gauges respond to the unbending of the beams.

Changes in the electrical resistivity of a specimen containing a propagating crack<sup>19</sup> depend upon applying a high constant direct current at each end of the specimen and measuring the potential difference across electrical leads situated at the opposite sides of the crack. The potential field in the region of the crack is disturbed by the presence of the latter and as the crack extends, the potential difference between the leads on opposite sides increases, the total current remains constant. This requires a reliable constant current source, and the technique is dependent in some degree upon the exact positioning of the leads and gives less reproducible results if crack branching occurs. The initial thought that the application of DC to the specimen may influence the electrochemistry of the stress corrosion reactions is not sustained in practice, and the technique can provide reliable data.

High-frequency stress waves are generated when stress corrosion cracks propagate in some materials, especially the high-strength steels when these undergo

hydrogen-induced cracking. The detection of these acoustic signals, which are filtered from lower amplitude background noise, affords a means of studying crack propagation.<sup>20</sup> While the technique involves the use of sophisticated and relatively costly equipment if it is to be correctly practiced, it has been suggested that it may also offer a means of distinguishing between active paths and hydrogen-embrittlement mechanisms of cracking.<sup>21</sup> However, that is not universally accepted, and the data from acoustic signals need treating with caution.<sup>22</sup>

#### **2.35.2.4 Effects of Surface Finish**

It is hardly surprising that the preparation of surfaces of plain specimens for stress corrosion tests can sometimes exert a marked influence upon the results. Heat treatments carried out on specimens after their preparation is otherwise completed can produce barely perceptible changes in surface composition, for example, decarburization of steels or dezincification of brasses, that promote quite dramatic changes in stress corrosion resistance. Similarly, oxide films, especially if formed at high temperatures during heat treatment or working, may influence results, especially through their effects upon the corrosion potential.

However, quite apart from these chemical changes at surfaces occasioned by the method of specimen preparation, physical effects may be important. Paxton and Procter<sup>23</sup> have prepared a review of what little is known about the effects of machining and grinding upon stress corrosion susceptibility, the most obvious effects being related to surface topography and the introduction of residual stresses into the surface layers. The former is more likely to be important in the higher strength notch-sensitive materials, while surface compressive stresses are likely to have the general effect of delaying or preventing failure.

#### **2.35.3 Choice of Environment**

Although the list of environments reported as promoting stress corrosion cracking in any alloy continues to grow with time, the concept of solution specificity remains in that not all corrosive environments will initiate or sustain stress corrosion cracking in all alloys. While it is inevitable that the environment will always remain as one of the variables that may need to be assessed by stress corrosion tests, nevertheless certain solutions, by their widespread use over many years, have tended to become standard test solutions for certain types of alloys. Thus, boiling

MgCl<sub>2</sub> solution for stainless steels, boiling nitrate solutions for carbon steels, and 3.5% NaCl for aluminum alloys, to mention but a few, have been extensively used, for example, in comparing the effects of metallurgical variables upon cracking propensities. Such approaches raise two questions: the first concerned with the extent to which 'standard' solutions prepared in different laboratories may be regarded as identical, and the second with the extent to which degrees of susceptibility of a range of alloys to cracking in one environment are related to cracking in a different environment.

While the relatively small differences that may be expected to occur between laboratories preparing a solution to the same specification often will not influence stress corrosion test results, there are situations where relatively small changes in environment can promote marked changes in cracking response. Thus, Streicher and Casale<sup>24</sup> have pointed to the potential problems associated with the use of nominally 42% boiling MgCl<sub>2</sub> in testing stainless steels. Since the hydrate of MgCl<sub>2</sub> is hygroscopic, solution preparation by weighing may lead to appreciable differences in boiling point and hence, times to failure in a stress corrosion test, so that it is preferable to prepare the solution by adding water to the hydrate to achieve a particular boiling point.

Similarly, pH variations resulting from either the initial preparation or from changes during a stress corrosion test may exert a marked influence upon results in some systems. Thus, the cracking of carbon steels in nitrates is markedly pH sensitive and, depending upon the volume of solution and the surface area of the specimen exposed, as well as upon the time involved in making the test, significant pH rises can occur, and cracking can cease as a result. Moreover, if tests are carried out with anodic stimulation, these effects may be aggravated, especially if the counter electrode is immersed in the test cell. In other cases, for example, the medium and higher strength steels, the initiation and maintenance of cracking frequently requires localized pH changes within the confines of the crack, and these can only occur if the initial conditions of exposure are appropriate.

The oxygen concentration of the solution, as in many instances of corrosion, can also be critical in stress corrosion cracking tests. Instances are available in the literature that show very markedly different test results according to the oxygen concentration in systems as widely different as austenitic steels immersed in chloride-containing phosphate-treated boiler water<sup>25</sup> and aluminum alloys<sup>26</sup> immersed in 3% NaCl.

The assumption that the relative cracking responses of a series of alloys will be the same irrespective of the environment to which they are exposed can be extremely dangerous. Many examples could be quoted of the dangers of drawing conclusions from tests in a given environment and applying these to a different situation, but some results by Lifka and Sprowls<sup>27</sup> will suffice. The results for the relative cracking susceptibilities of three aluminum alloys subjected to different exposure conditions are shown in **Figure 12**, which indicate that an intermittent spray test using acidified 5% NaCl solution gives the same order of susceptibility for the three alloys as was observed in outdoor exposure tests at three different locations. On the other hand, an alternate immersion test in 3.5% NaCl, widely used for testing aluminum alloys, places the alloys in a completely different order of susceptibility. This single example will suffice to indicate the necessity for simulating service conditions as closely as possible where laboratory data are to be used for selection or design in relation to industrial equipment.

While the dangers inherent in using standardized environments in relation to environment-sensitive fracture are readily indicated by many examples that can be quoted, there remains a problem in relation to alloy development where possible service environments may not always be identifiable at the time of the development program. In such circumstances, it appears desirable that an alloy should be assessed in a range of environments, but even then, it is necessary for realism to be injected into the program if an excessively large number of test environments are

not to be involved. The potential dependence of cracking, with its implications for dissolution and film-forming reactions or the discharge of hydrogen, suggests that the solution pH is also likely to exert significant influence upon cracking. Plots of cracking domains on potential–pH diagrams sometimes indicate correlations with certain reactions, and this may be useful in guiding a testing program,<sup>28</sup> that is, involving solutions of different pH values and exploring the cracking propensity as a function of potential.

The importance of potential cannot be over emphasized, and some aspects of this part of stress corrosion testing may be conveniently discussed in the context of **Figure 13**. This shows the different potential ranges for the cracking of ferritic steel according to the environment in tests involving potentiostatic control. Also shown are the free corrosion potentials for that steel in the different solutions. These indicate that while failure would occur in the nitrate at the free corrosion potentials, this would not be so in the hydroxide or carbonate–bicarbonate solution. This does not mean that carbon steels will never fail by stress corrosion in these two environments at the free corrosion potential, since the latter is, of course, dependent upon the composition of the steel, its surface condition, the composition of the environment, and other factors. It is possible, therefore, that as the result of, say, small additions to the environments, added intentionally or present as impurities, the corrosion potential can be caused to be within the cracking range, or that as a result of small additions to a steel, the corrosion potential may fall outside the cracking range. Quite small changes in

**Figure 12** Relative resistance to stress corrosion cracking of three aluminum alloys subjected to different environments. The stress levels employed corresponded to 75, 50, and 25% of the respective transverse yield strengths. Reproduced from Lifka, B. W.; Sprowls, D. O. Stress Corrosion Testing, ASTM STP No. 425, 1966; p. 342.

**Figure 13** Current density differences between fast and slow sweep rate polarisation curves and stress corrosion cracking susceptibility as a function of potential for C-Mn steel in nitrate, hydroxide, and carbonate-bicarbonate solutions.

potential, often only a few tens of millivolts, can therefore produce dramatic changes in cracking response and point to the necessity, especially in laboratory tests attempting to simulate a service failure, of reproducing the potential with precision.

## 2.35.4 Stress Corrosion Test Methods

### 2.35.4.1 Types of Test Cells

The cells that contain the specimen and environment for stress corrosion tests often need to be more than a

vessel made in some substance, usually glass, that is inert to the environment and which produces no electrical response upon the test specimen. Where cracking is initiated at surfaces through which heat transfer occurs, it may be necessary to design a cell in which such an effect is incorporated, since the concentration of substances in solution that may occur at an interface through which heat passes, may play a significant role in promoting cracking, especially if surface deposits allow concentration by evaporation while preventing mixing with the bulk or the environment. The cracking of riveted mild-steel boilers and the concentration of carbonate-bicarbonate

solutions under pipeline coatings to produce cracking in high-pressure gas transmissions lines are significant examples. Dana<sup>29</sup> has developed a method for simulating the conditions for cracking of stainless steels in contact with thermal insulating materials, while concentration in leaking boiler seams is simulated in the 'embrittlement detector' developed by Schroeder and Berk.<sup>30</sup>

Such test cells involve, among other things, a crevice, the essence of which is that the volume of solution that it contains is relatively small compared with the area of exposed metal, a ratio that may influence stress corrosion test results determined in more conventional cells where crevices do not exist. The experiments of Pugh *et al.*,<sup>31</sup> on the stress corrosion of 70–30 brass in ammoniacal solutions of various volumes are particularly instructive in indicating how this ratio may influence results, the time to failure varying by about an order of magnitude for a similar change in solution volume. Changes in the surface area of exposed specimens, apart from the effects already implied, may influence the cracking response for other reasons, as shown by the results of Farmery and Evans<sup>32</sup> for an Al–7Mg alloy immersed in a chloride solution. They found that coupling unstressed to stressed specimens of varying area ratio influences failure times, relatively shorter times being obtained when the area of unstressed to stressed specimen was large.

#### 2.35.4.2 Initiation of Stress Corrosion Tests

It may be felt that the initiation of a stress corrosion test involves no more than bringing the environment into contact with the specimen in which a stress is generated, but the order in which these steps are carried out may influence the results obtained, as may certain other actions at the start of the test. Thus, in outdoor exposure tests, the time of the year at which the test is initiated can have a marked effect upon the time to failure,<sup>26</sup> as can the orientation of the specimen, that is, according to whether the tension surface in bend specimens is horizontal upwards or downwards or at some other angle. However, even in laboratory tests, the time at which the stress is applied in relation to the time at which the specimen is exposed to the environment may influence results. Figure 14 shows the effects of exposure for 3 h at the applied stress before the solution was introduced to the cell, upon the failure of a magnesium alloy immersed in a chromate–chloride solution. Clearly, such prior creep extends the lifetime of specimens and raises the

**Figure 14** Effect of delay period between application of load and introduction of solution to test cell in the failure of a Mg–7Al alloy exposed to a chromate–chloride solution. Reproduced from Wearmouth, W. R.; Dean, G. P.; Parkins, R. N. *Corrosion* **1973**, 29, 251.

threshold stress very considerably, and since other metals are known to be strain-rate sensitive in their cracking response, it is likely that the type of result apparent in Figure 14 is more widely applicable.

#### 2.35.4.3 Hydrogen Embrittlement Tests

The absorption of hydrogen by various materials, including high-strength steels, results in loss of ductility, which in turn can result in cracking and fracture when the metal is subjected to a sustained tensile stress. Hydrogen may be introduced into these various alloys from the gas phase (during manufacture or welding), or from aqueous solution during surface treatment (pickling, plating, and phosphating) or from the environment during a spontaneous corrosion process in which the development of acidity within the crack results in hydrogen evolution and absorption. Various test methods<sup>33</sup> may be used to evaluate the effect of hydrogen on the properties of alloys, including some *ad hoc* tests that were specifically developed for high strength steels.

Although similar constant-load test rigs are used for both active-path corrosion and hydrogen stress cracking, there is one fundamental difference in the test procedure. In the case of active-path corrosion testing, it is always carried out in the presence of the corrosive environment, but in the case of hydrogen-related cracking, testing may be carried out after hydrogen has been introduced into the alloy either deliberately by gaseous or cathodic charging, or following processes such as welding, pickling, or electroplating. However, with precharged specimens, loss

of hydrogen may occur<sup>34</sup> when they are removed from the environment, resulting in the entry of that substance and so, sustained-load tests are also carried out in the presence of an environment (gaseous or aqueous) so that hydrogen is introduced into the test piece during the application of the tensile stress.

#### 2.35.4.4 Dynamic Tests

All of the properties evaluated by the conventional tensile test (yield strength, tensile strength, elongation, and reduction in area) are affected by the presence of hydrogen, but in the case of the tensile strength and yield strength, the effect is significant only when the steel has a very high tensile strength and has been severely embrittled. On the other hand, the reduction in area, and, to a lesser extent, the elongation may be used for detecting embrittlement. Hobson and Sykes<sup>35</sup> found that with low-carbon steels there was an almost linear relationship between reduction in area and hydrogen content of the steel. Slow strain-rate tests are sometimes employed in testing materials (and not only steels) after preexposure to a source of hydrogen. The strain rate may be critical in that not only can it be too high but also, if it is too low the hydrogen may diffuse out of the specimen before cracking occurs.

Various types of bend tests have been used to evaluate embrittlement. Beck *et al.*<sup>36</sup> used thin strip specimens and determined the decrease in height,  $\Delta h$ , at fracture when the specimen was bent by compressing it at a constant rate in a tensile testing machine (Figure 15). The decrease in height,  $\Delta h$ , gives a measure of the embrittlement, the maximum elongation of the outside fiber of the specimen being calculated from the radius of curvature at maximum bending. In general, the ductility is found to increase with the rate of straining, and for this reason, high-strain-rate tests, such as impact tests, are insensitive to hydrogen embrittlement. Where the material is available only in the form of tubing, semicircular specimens may be used in place of flat strips in the compression bend test. The total cross-head travel from the unstressed height along the diameter to the point of fracture gives a measure of embrittlement, which may be compared with that obtained from an unembrittled specimen of the same steel.

A constant-rate bend-test machine, which provides an effective method for testing highly embrittled steel wires of high-tensile strength, was designed by Zapffe and Haslem<sup>37</sup> (Figure 16). The motor *A* pulls a chord attached to the traveling arm *D* that rotates about a

**Figure 15** Bend test using a tensile testing machine. Reproduced from Beck, W.; Klier, E. P.; Sachs, G. *Trans. AIME* 1956, 206, 1263.

**Figure 16** Constant-rate bend-test for determining hydrogen embrittlement of wires. *A*, drive unit; *B*, pulley; *C*, semicircular base; *D*, traveling arm; *E*, axial pin; *F*, fixed arm; *G*, wire specimen. Reproduced from Zapffe, C. A.; Haslem, M. E. *Trans. AIME* 1946, 167, 281.

pivot pin. The wire specimen *G* (1.6 × 100 mm) is inserted in *D* and is supported by the fixed arm *F*, the arrangement being so designed that tensile or torsional stresses are avoided. The specimen is thus bent around the pivot pin *E* (radius 1.6 mm) at a constant rate, the angle of bend to cause fracture giving a measure of its ductility. Since ductility increases with rate of straining, the bending rate must be slow and (4%) is

considered to be suitable for detecting embrittlement. A similar machine has been used for studying the embrittlement of spring steel strip after hydrogen has been introduced by cadmium plating.

An alternative procedure is the reverse-bend test in which the specimen in the form of wire or strip is bent repeatedly backward and forward over a mandrel until it fractures, the number of bends

**Figure 17** Schematic representation of delayed failure characteristics of a hydrogenated high-strength steel.

indicating the degree of embrittlement. However, this method is considered to be less sensitive than the single-bend test.

#### 2.35.4.5 Static Tests

Whereas ductile materials, such as iron and mild steel, are often considered not to crack when charged with hydrogen and subjected to a tensile stress below the yield stress, the position is different with high-strength ferrous alloys where, depending on the strength of the steel and the hydrogen content, failure may occur well below the yield stress. However, the fracture process is not instantaneous, and there is a time delay before cracks are initiated; for this reason, the phenomenon is sometimes referred to as 'delayed failure.'

In the majority of cases, the tests are conducted using a dead-weight lever-arm stress-rupture rig with an electric timer to determine the moment of fracture, but a variety of test rigs similar to those shown in [Figure 1\(g\)](#) are also used. The evaluation of embrittlement may be based on a delayed-failure diagram in which the applied nominal stress versus time to

**Figure 18** Methods of gripping specimens in order to avoid bending stresses: (a) Device for threaded end specimens, and (b) device for shouldered-end specimens. Reproduced from Stress Corrosion Testing, ASTM STP No. 425, 1967.

failure is plotted, [Figure 17](#), or the specimen may be stressed to a predetermined value (say 75% of the ultimate notched tensile strength) and is considered not to be embrittled if it shows no evidence of cracking within a predetermined time (say 500 h). Troiano<sup>38</sup> considers that the nature of delayed fracture failure can be described by four parameters (see [Figure 17](#)):

1. the upper critical stress corresponding to the fracture stress of the unembrittled notched specimen;
2. the lower critical stress, which is the applied stress below which failure does not occur;
3. the incubation period or the time required for the formation of the first crack;
4. the failure time or the time for specimen failure at a given applied stress; in the intermediate stress range, this includes a period of relatively slow crack growth.

During the constant-load test, it is essential that only axial tensile stresses are applied, as any bending stresses that are introduced will result in a higher true stress than that calculated. For this reason, the ends of the specimens and the grips must be designed to avoid bending stresses. The ASTM Standard E8 (Standard Test Methods for Tension Testing of Metallic Materials) specifies that in the case of specimens with threaded ends the grips should be attached to the heads of the testing machine through properly lubricated spherical-seated bearings and that the distance between the bearings should be as great as is feasible ([Figure 18](#)).

In order to simplify the test procedure, a number of investigators have designed test rigs in which the bulky lever arm is replaced by a loading nut, the stress in the specimen being determined by means of strain gauges; these rigs are similar in principle to those shown in [Figure 1\(g\)](#). [Figure 19](#) shows a spring-loaded rig that was used by Cavett and van Ness<sup>39</sup> to study the embrittlement produced by hydrogen gas at high pressures, in which the tensile load is applied by compressing a heavy-duty spring.

Raring and Rinebold<sup>40</sup> have devised a method in which the specimen is supported along the diameter of a steel loading ring, [Figure 20](#), and the stress is applied by tightening the bottom nut until the diameter corresponds with the required load. The sudden release of elastic energy stored within the ring when the specimen fractures results in displacement of the tightening nut, and this is used to actuate a micro-switch and timer. Williams *et al.*<sup>41</sup> have used notched 'C'-rings, the stress being applied by tightening the

**Figure 19** Spring-loaded rig for sustained load testing of a steel specimen in gaseous hydrogen at high pressure. Reproduced from Cavett, R. H.; van Ness, H. C. *Welding J.* (research supplement) **1967**, 42, 317.

**Figure 20** Loading-ring method of stressing a specimen. Reproduced from Raring, R. H.; Rinebold, J. A. *ASTM Bulletin No. 213*, 1956.

nut of a calibrated loading bolt that passes through the diameter of the 'C' ring, [Figure 21](#). The strain gauges attached to the bolt form two arms of a Wheatstone bridge circuit and to compensate for temperature

**Figure 21** Notched 'C'-ring specimen with attached strain gauges.

**Figure 22** Correction factor Z for calculating stress in 'C'-ring tests.

changes, the other two arms consist of two identical strain gauges attached to a similar unstrained bolt.

## Appendix A: Stresses in Bent Specimens

In each of the following equations:  $\sigma$  = maximum tensile stress,  $E$  = modulus of elasticity, and  $t$  = specimen thickness.

### A.1 Two-point bending, Figure 1(a):

$$L = \frac{k.t.E}{\sigma} \sin^{-1} \left( \frac{H.\sigma}{k.t.E} \right)$$

where  $L$  = specimen length,  $k$  = constant (1.280), and  $H$  = holder span.

### A.2 Four-point bending, Figure 1(b):

$$\sigma = \frac{12E.t.y}{3L^2 - 4A^2}$$

where  $y$  = maximum deflection,  $L$  = distance between outer supports, and  $A$  = distance between inner and outer supports.

### A.3 'U'-bends, Figures 1(d) and 1(e):

Applied strain  $\epsilon = t/2r$ , when  $t < r$ , where  $r$  = radius of curvature at section of interest.

### A.4 'C'-rings, Figure 1(c):

$$\sigma = \frac{4E.t.Z.\Delta}{\pi D^2}$$

where  $\Delta = OD_f - OD_i$ ,  $OD_f$  = final outside diameter of stressed 'C'-ring,  $OD_i$  = initial outside diameter of unstressed 'C'-ring,  $D$  = mean diameter, that is,  $(OD - t)$ , and  $Z$  = a correction factor, related to  $D/t$  as indicated in Figure 22.

## Glossary

- Exceedance** The amount by which a data value exceeds a selected threshold.
- Extrapolation** The process of predicting the value of some quantity of interest over a region (interval of space and/or time) that is outside the region of observation or inspection.
- Extreme value** The largest (else smallest) number in a data set.
- Likelihood** The joint probability distribution for the sampled data, considered as a function of the parameters of this distribution.
- Operational failure rate** The reciprocal of the mean time between operational failures of the function of a system that is subject to preventive maintenance such as inspection and repair.
- Outlier** A discordant or suspect data value.
- Poisson process** A sequence of events occurring purely at random in time or over an area at a constant mean rate.
- Probability** The relative 'long-run' frequency of occurrence of an outcome from many repetitions of a test or experiment, or the degree of one's current belief that a statement is true. Measured on a scale from 0 to 1, where 0 indicates that the outcome of interest cannot occur and 1 indicates that it must occur.

## Abbreviations

- CDF** Cumulative distribution function
- EV** Extreme value distribution
- F dn** Fisher's variance-ratio distribution
- GEV** Generalized extreme value distribution
- GPD** Generalized pareto distribution
- IRIS** Internal rotary inspection system
- LOTIS** Laser optical tube inspection system
- MAT** Minimum allowable thickness
- ML** Maximum likelihood
- MTBOF** Mean time between operational failures

**NDT** Nondestructive testing (also known as nondestructive examination, NDE)

**NWT** Nominal wall thickness

**PDF** Probability density function

**RWT** Remaining wall thickness

**S-IDAP** Shell inspection design analysis and plotting package

**t dn** Student's  $t$  distribution

**TML** Thickness measurement location

**WT** Wall thickness

## Symbols

- A** Extrapolation area
- a, b** Intercept and slope for data regression line
- C<sub>f</sub>** Cost of failure due to a crack
- C<sub>p</sub>** Cost of inspection for cracks including the repair of crack defects
- C(T)** Long-run cost per unit time of policy that inspects every  $T$  time units
- F<sub>max,τ</sub>(z)** Distribution function of the maximum crack depth at inspection at time  $T$
- F<sub>T</sub>(z)** Unconditional distribution of the crack depth at inspection at time  $T$
- F(y)** Probability model cumulative frequency distribution (cdf,  $\Pr(Y < y)$ )
- f(x, θ), F(x, θ)** Density and distribution function with parameter  $\theta$
- F(x), f(x), f(x|·)** Distribution function, density, and conditional density
- F<sub>n</sub>(y)** Sample cdf for  $n$  data values
- G<sub>T</sub>(z; T - x)** The distribution of crack depth at inspection at time  $T$  conditional on initiation of a crack at time  $x$
- G(Z; τ)** Distribution of crack depth for a crack that has been growing for time  $\tau$
- N<sub>t</sub>** Number of cracks at time  $t$
- P<sub>WT</sub>( )** Density function of initial wall thickness
- p( )** Posterior or prior density function
- Pr(A)** Probability that event A occurs
- Pr(A|B)** Probability that A occurs given that B occurs

<b>Pr(A &amp; B), Pr(A, B)</b>	Probability that both A and B occur
<b>R</b>	Half-width of uniform error range
<b>S(t)</b>	Survivor function ( $\Pr(T > t) = 1 - F(t)$ )
<b>S<sup>2</sup></b>	Sample variance of data
<b>T</b>	Optimum inspection interval
<b>u</b>	Threshold wall loss
$\bar{x}, \bar{y}$	Means or averages for sample data
<b>X<sub>(p)</sub></b>	The $p$ th quantile of the maximum wall loss distribution
<b>y(i)</b>	$i$ 'th order statistic, the $i$ 'th sample value in ordered data $y(1) < y(2) < \dots$
<b>z<sub>f</sub></b>	Critical crack depth: if $Z > z_f$ , then failure occurs
<b><math>\alpha\alpha</math></b>	Intercept for model regression line or similar <i>else</i> scale parameter for Extreme Value distribution
<b><math>\beta\beta</math></b>	Slope for model regression line or similar
<b><math>\delta, \alpha</math></b>	Location and scale parameters of a GEV or GPD
<b><math>\Delta, \hat{\Delta}</math></b>	Change and estimated change in extreme value mode between inspections
<b><math>\varepsilon</math></b>	Measurement error effect on the mode of a Gumbel distribution
<b><math>\gamma\gamma</math></b>	Euler constant, 0.57721...
<b><math>\gamma, \alpha_0, \beta</math></b>	Parameters of Weibull distribution for $G_T(z; T - x)$
<b><math>\kappa</math></b>	Shape parameter of a GEV or GPD
<b><math>\lambda\lambda</math></b>	Mean event rate for a Poisson process (e.g. pit initiation or crack initiation)
<b><math>\mu</math></b>	Mean of a probability distribution
<b><math>\hat{\mu}, \hat{\sigma}</math></b>	Maximum likelihood estimates of distribution parameters
<b><math>\varphi()</math></b>	Density of wall loss measurement error
<b><math>\Theta, \theta, \theta_1, \theta_2</math></b>	Possible values of the Bernoulli parameter
<b><math>\rho\rho</math></b>	Coefficient of Variation, $\sigma/\mu$
<b><math>\sigma</math></b>	Standard deviation (square-root of variance) <i>else</i> scale parameter for a distribution
<b><math>\sigma^2, \sigma_c^2, \sigma_e^2</math></b>	Variance and variance components of a Normal distribution, $N(\mu, \sigma^2)$
<b><math>\xi</math></b>	Bound for extreme value distribution

## 2.36.1 Introduction

Statistical techniques are used extensively across the full range of scientific and engineering disciplines. More often than not, the results of experimental studies are reported in terms of averages, best-fit lines, confidence limits, and distribution functions. The special relevance of statistics to corrosion was

identified as early as 1933,<sup>1</sup> and the application of extreme value analysis techniques to some corrosion engineering problems was introduced in the 1950s.<sup>2,3</sup> Statistical approaches were then more widely adopted and developed in Japan, both in the study of localized corrosion processes<sup>4,5</sup> and for remnant life prediction in an engineering context.<sup>6</sup> The 1980s and 1990s saw increasing academic activity,<sup>7-9</sup> and recently there have appeared a small number of guidelines and standards for the practical applications of these techniques.<sup>10-12</sup>

Other chapters in this book describe the state of the art in corrosion modeling, but here we briefly mention a few examples where in statistical techniques have proved particularly useful. In modeling pitting corrosion of stainless steels, it is common to assume that pit initiation is a *Poisson process* occurring randomly in time and at sites distributed randomly across the sample surface,<sup>13-15</sup> although interactions between pits are now being considered more significant.<sup>16,17</sup> Similarly, *percolation theory*<sup>18</sup> has been used to explain the critical Cr concentration for the passivation of stainless steels in dilute acids,<sup>19,20</sup> the degree of grain boundary sensitization required for intergranular SCC of 304 stainless steel in thiosulfate solutions,<sup>21</sup> the mechanism of pit initiation for stainless steels in chloride solutions,<sup>22</sup> and the critical compositional thresholds associated with dealloying processes.<sup>23,24</sup> Of course, *Monte-Carlo (MC) techniques*<sup>25</sup> are frequently applied to enable the computer simulation of these and other corrosion processes; for example, **Figure 1** shows the results of an MC simulation of the passivation of Fe–Cr alloys.

Statistical approaches are frequently applied to the analysis of the results from the experimental studies of pitting corrosion, and the so-called ‘electrochemical noise’ monitoring is fundamentally dependent on statistical theory. Both these application areas are covered in some detail later. However, the most economically important use of statistics in corrosion is undoubtedly in the analysis of inspection results to estimate the in-service corrosion rate of industrial plants. These results are used to determine the planned replacement and future inspection strategies for plants all over the world, with enormous safety, financial, and environmental consequences potentially arising from poor decisions. In this context, it is natural to consider extreme corrosion events so that extreme value analysis has found wide application. In this chapter, we provide a basic introduction to the underlying mathematics behind the most commonly used techniques in the statistical

**Figure 1** Surface exposed Fe (grey) and Cr (black) atoms after 100 000 time steps in a dissolution simulation involving 17 261 atoms in a bcc lattice: (a) 3 at.% Cr; (b) 18 at.% Cr. This simulation is based on the method described in Qian *et al.*,<sup>20</sup> and it shows passivation when the Cr concentration is above the relevant percolation threshold,  $P_c(1,2) = 17.2$  at.%.

evaluation of corrosion data, but we focus, in particular, on those methods that have either been customized to a significant extent for specific applications in corrosion, or seem most likely to be further developed by the corrosion community in the future.

### 2.36.2 Basic Terminology and Methods

This is an introduction to the relevant statistical terminology and methods discussed in this chapter, as can be found in a fuller form in an introductory text book or at online resources.<sup>26,27</sup> Dedicated statistical software packages, such as SPSS, MINITAB, SAS, or GENSTAT, are also widely available and are usually preferable for implementing statistical techniques. Extensions of these ideas and nomenclature to allow for other probability distributions and contexts are introduced as and when they appear in this chapter.

#### 2.36.2.1 The Normal Distribution and Associated Distributions

Statistical methods are designed to explore the interface between data and models. The simplest standard model is the Normal (or Gaussian) distribution, as illustrated in **Figure 2** with an example dataset comprising 75 measurements of crack depth on circumferential welds on piping at various locations inside a nuclear power plant facility.

Note that although the data are clearly not ‘a perfect fit’ to the model, they can nevertheless be shown to be compatible with these model assumptions.

**Figure 2** An example of a Normal (or Gaussian) distribution. The dataset comprises 75 measurements of crack depth on circumferential welds on piping inside a nuclear power plant.

We write  $Y \sim N(\mu, \sigma^2)$  to be read as ‘the random variable  $Y$  has a Normal distribution with mean  $\mu$  and variance  $\sigma^2$ .’ However, there are two possible ‘outliers’ in the right-hand ‘tail’ of the distribution at a depth of 22  $\mu\text{m}$ , which might warrant a validity check and an assessment of any special circumstances at that measurement location. The model allows us to make statements such as ‘There is a 95% probability that the next observation on  $Y$  will lie in the interval  $\mu \pm 1.96\sigma$ .’ Note that  $\sigma$  is called the standard deviation of  $Y$  and is measured in the same units. Replacing

1.96 ( $\sim 2$ ) with 1.64 produces a 90% interval size, while 3.29 ( $\sim 3$ ) produces 99%, and 4.89 ( $\sim 5$ ) leaves just a one in a million chance of landing outside of the interval. The smooth curve drawn in **Figure 2** is called the probability density function (PDF), and for the Normal distribution, this has formula

$$f(y) = \frac{1}{\sqrt{2\pi}\sigma} \exp \left[ -\left( \frac{y - \mu}{\sigma} \right)^2 \right] \quad [1]$$

Probabilities for this or any other random variable are obtained by integrating the relevant PDF over the chosen interval. In particular, the cumulative distribution function (CDF) is defined by

$$\Pr(Y \leq y) = F(y) = \int_{-\infty}^y f(y) dy \quad [2]$$

This probability may or may not have a simple formula. For the Normal distribution, access is required to a table of values for the standard distribution with mean zero and standard deviation one. When the measured variate is time, especially a failure time, then  $S(t) = \Pr(T > t) = 1 - F(t)$  is commonly called the Survivor function.

A random sample of observations  $y_1, y_2, \dots, y_n$  on any such random variable  $Y$  has sample mean (or average)  $\bar{y} = (y_1 + y_2 + \dots + y_n)/n$ , which can be used to estimate the population mean,  $\mu$ , and we write  $\hat{\mu} = \bar{y}$ . The distinction between capital letters ( $Y$ , standing for the name of the random variable) and lower-case letters ( $y$  for the collected data) is frequently dropped, whereas the distinction between Latin letters (such as  $y$  and  $s$  for data) and Greek letters (such as  $\mu$  and  $\sigma$  for model parameters) is always vital and should only be discarded when the context and intent is clear – although for simplicity of presentation, this will usually be assumed to be the case in most of this chapter. By the Central Limit Theorem, almost all sample means,  $\bar{y}$ , have approximately (although exactly so if  $Y$  is itself Normal) a Normal distribution, with mean  $\mu$  and variance  $\sigma^2/n$  – and hence standard deviation (or ‘standard error’) equal to  $\sigma/\sqrt{n}$ , which tends to zero as  $n$  increases.

The data will also have their own sample variance, given by

$$s^2 = \frac{1}{(n-1)} \sum_{i=1}^n (y_i - \bar{y})^2 \quad [3]$$

which provides an ‘unbiased’ estimate of the population variance  $\sigma^2$ , where we write  $\tilde{\sigma}^2 = s^2$ , which then provides an estimate  $s/\sqrt{n}$  of the ‘standard error of the mean’. The divisor ‘ $n - 1$ ’ is called the ‘degrees of freedom’ for the numerator and will change as more

parameters (currently only one, namely  $\mu$ ) are introduced into the model of the population mean. When  $Y$  is Normal, a 95% (say) ‘confidence interval’ for the true mean,  $\mu$ , is  $\hat{\mu} \pm t\sigma/\sqrt{n}$ , where  $t$  comes from tables for the  $t$ -distribution, with  $t = 1.96$  for a large  $n$  when this can also be used for other sampled distributions.

Proposed values of  $\mu$  (such as zero, for example), which lie outside of this interval, are said to be rejected at a 5% significance level. Conversely, the confidence interval could alternatively be derived from the formalities of the significance test.

The mean  $\mu$  represents the deterministic part of the model and can be expanded – as can the noise (or random) component  $\sigma^2$  – to incorporate covariate data  $x_1, x_2, \dots, x_n$  collected along with  $y$  on a  $p$ -vector  $x = (x_1, x_2, \dots, x_p)^T$ . Such information was available for the data on  $Y$ , as summarized in **Figure 2**, namely ‘location,’  $x_1 = 1$  or  $2$ , and  $x_2 =$  ‘working hours’; and this was initially absorbed into a more complex model of  $Y$ , incorporating parallel linear relationships between  $Y$  and  $x_2$ . The effect of location (reactor number) was found to be statistically nonsignificant, leaving just the simple regression line through the data displayed in **Figure 3**. The fitted model is

$$y_i = 4.7609 + 0.1875x_{2i} + e_i, \text{ where}$$

$$e_i \sim N(0, 0.993^2), i = 1, \dots, n \quad [4]$$

The histogram of the fitted residuals  $\{e_i\}$  is shown in **Figure 4**, where it can be seen that the visual fit for a Normal distribution is superior to that for the original  $y$  data seen in **Figure 2** – as is often the case with the residuals from more complex models, thereby making the assumption of Normality of the random component of the model more plausible. However, the two outliers are still noticeable and may warrant special attention. A typical definition of an outlier is any data point for which the modulus of the associated residual term in the fitted model exceeds  $3\sigma$ ; refer to the book on outliers by Barnett and Lewis.<sup>28</sup>

Note that when modeling the variance in a corrosion context, it can be important to distinguish between system or corrosion noise,  $\sigma_c^2$ , and measurement error,  $\sigma_e^2$ . These may add to give  $\sigma^2 = \sigma_c^2 + \sigma_e^2$ ,  $\sigma^2 = t\sigma_c^2 + \sigma_e^2$ , or  $\sigma^2 = t^2\sigma_c^2 + \sigma_e^2$ , depending on the context or assumptions – where  $t$  is the exposure time.

It is often useful to reorder the data by size, with notation  $y_{(1)} \leq y_{(2)} \leq \dots \leq y_{(n)}$ , implying that  $y_{(1)}$  is the data minimum,  $y_{(n)}$  is the data maximum, and more generally,  $y_{(i)}$  is called ‘the  $i$ th’-order statistic. Plotting  $y_{(i)}$  against  $i/n$  gives the sample cumulative distribution function,  $F_n$  where

**Figure 3** For the data shown in Figure 2, the effect of location on crack depth was found to be statistically nonsignificant, leaving just the simple regression line shown here for the effect of ‘working hours.’

**Figure 4** The histogram for the fitted residuals  $e_i$  from the linear regression of Figure 3. The visual fit for a Normal distribution is superior to that for the original crack depth data seen in Figure 2. However, the two outliers are still noticeable and may warrant special attention.

$$F_n(y) = i/n, \mathcal{Y}_{(i)} < y \leq \mathcal{Y}_{(i+1)} \quad i = 0, 1, 2, \dots, n,$$

with  $\mathcal{Y}_{(0)} = -\infty, \mathcal{Y}_{(n+1)} = \infty$

Alternatively, since  $E[F(\mathcal{Y}_{(i)})] = i/(n+1)$ ,  $i = 1, 2, \dots, n$ , plotting  $\mathcal{Y}_{(i)}$  against  $i/(n+1)$  and connecting points directly by straight lines or a smooth curve will provide an approximately unbiased estimate  $\hat{F}$  of the population cumulative distribution function,  $F$ , with  $\hat{S} = 1 - \hat{F}$  for the Survivor function. Also, plotting  $\mathcal{Y}_{(i)}$  against  $F^{-1}(i/(n+1))$ , when  $F$  is known (perhaps only up to location and scale), should give an approximately straight line if the assumed distributional form is correct. The intercept and slope of

this line can provide estimates of the unknown location and scale parameters. This technique can be implemented algorithmically or *via* the appropriate probability paper.

Discrete probability distributions can be used for counting pits, failures, or other corrosion-induced events. A standard model is the Binomial distribution

$$p_r = \Pr(X = r) = {}^nC_r p^r q^{n-r},$$

$$q = 1 - p, r = 0, 1, \dots, n \quad [5]$$

for the number of ‘successes’  $X$  in  $n$  independent trials with a constant probability of success,  $p$ . This distribution has mean  $\mu = np$  and variance  $\sigma^2 = npq$ , and for a large  $n$ , this can be approximated by a Normal distribution with the same mean and variance by replacing ‘ $r$ ’ with the interval  $r \pm \frac{1}{2}$  – except for ‘rare events’ with  $\mu < 5$  when a Poisson distribution can be used. For event counts in random samples of  $n$  objects from a finite population of  $N$  objects, such as a boiler with  $m$  ‘failed tubes’ out of  $N$ , we can use the hypergeometric distribution

$$p_r = {}^mC_r {}^{N-m}C_{n-r} / {}^NC_n, \max\{0, m+n-N\}$$

$$\leq r \leq \min\{m, n\} \quad [6]$$

This distribution has mean  $\mu = mn/N$  and variance  $\sigma^2 = npq[(N-n)/(N-1)]$ , where  $p = (m/N)$ ,  $q = 1 - p$ , and this can be approximated by a binomial – and hence by Normal or Poisson distributions as appropriate – for a large enough  $N$ .

### 2.36.2.2 Linear Regression

The statistical methods in 'linear regression' cover a very wide range of models though the default assumption is a simple 'straight line regression,' which has the form  $y = \alpha + \beta x$ . The textbook by Freund and Wilson<sup>29</sup> provides an introduction to this topic, with a more extensive treatment in Neter *et al.*<sup>30</sup> The standard *straight line regression* model can be written as

$$y_i = \alpha + \beta x_i + e_i, \text{ where } e_i \sim N(0, \sigma^2),$$

$$i = 1, \dots, n \quad [7]$$

The least-squares estimates  $a$  and  $b$  of the intercept  $\alpha$  and slope  $\beta$  and the unbiased estimate of the residual variance  $\sigma^2$  are given by

$$b = \sum (x_i - \bar{x})(y_i - \bar{y}) / \sum (x_i - \bar{x})^2;$$

$$a = \bar{y} - b\bar{x}; \hat{\sigma}^2 = \sum (y_i - \hat{y}_i)^2 / (n - 2) \quad [8]$$

where  $\hat{y}_i = a + bx_i$  is the predicted value of  $y_i$  from the fitted model. Confidence limits about the line and prediction limits for future observations can be constructed. Formulae with further explanatory discussion are supplied in an example of straight line regression analysis of weight loss data, as is given later in [Section 2.36.3.2.1](#). Variants on this model are parallel regressions  $y_j = \alpha_j + \beta x_i, j = 1, 2$  or broken-line regressions

$$y = \alpha_1 + \beta_1 x \text{ for } x < x^* \text{ then } y = \alpha_2 + \beta_2 x \text{ for}$$

$$x \geq x^* = (\alpha_2 - \alpha_1) / (\beta_1 - \beta_2) \quad [9]$$

When duplicate observations are available for at least one fixed value of  $x$  and there are more than two distinct  $x$  values, then this will provide an independent estimate of the residual variance, enabling 'analysis of variance' techniques to be used to test the 'goodness-of-fit' of a straight line to the data. This method can be extended to more complex models.<sup>30</sup>

The *polynomial regression* model is given by

$$y_i = \alpha + \beta_1 x_i + \dots + \beta_k x_i^k + e_i \quad (i = 1, \dots, n) \quad [10]$$

In this model,  $x$  is called a *genuine* variable, while its powers,  $x^2, \dots, x^k$  are called *carrier* variables. This model can be used when searching for a local optimum in a dataset, and the most important special case is *quadratic regression*, for which  $k = 2$ .

Finally, we have *general linear regression*, for which

$$y_i = \alpha + \beta_1 x_{1i} + \beta_2 x_{2i} \dots +$$

$$\beta_k x_{ki} + e_i \quad (i = 1, \dots, n) \quad [11]$$

where some of the  $x_j^i$  s may be *genuine* physically distinct variables (such as temperature or pressure) and some may be *carriers* (such as powers or interaction terms such as temperature.pressure) or *indicators* of qualitative variates (such as location or manufacturer). When all the  $x_j^i$  s ( $j = 1, \dots, k$ ) are genuine, this model is called *multiple linear regression*.

These models are best fitted using a standard statistical package, which will supply the fitted parameters along with their standard errors, confidence intervals, and tests for goodness of fit. Note that in a model-fitting context, a nonlinear model is one where the unknown parameters (conventionally denoted by Greek letters) occur in a nonlinear fashion, as, for example, in the models  $y = \alpha e^{\beta x}$  or  $y = \alpha x / (\beta + x)$ .

### 2.36.2.3 Poisson Process Modeling

If 'events,' such as pits or cracks, occur 'purely at random' along a line, or in time, or over a surface – but at a constant mean rate, say  $\lambda$  – then they are said to follow a (homogeneous) 'Poisson process.' The count, say  $X$ , of events in any fixed interval/area of size  $t$  then follows a Poisson distribution:

$$\Pr(X = r) = \mu^r \exp(-\mu) / r!,$$

$$r = 0, 1, \dots; \mu = \lambda t \quad [12]$$

This distribution has mean and variance equal to  $\mu$  and can be approximated by a Normal distribution for a large  $\mu$ . The gaps,  $t$ , between such events along a single axis will follow an exponential distribution with PDF

$$f(t) = \lambda e^{-\lambda t}, t > 0 \quad [13]$$

This distribution has mean and standard deviation equal to  $1/\lambda$ . If the mean event rate  $\lambda$  varies, then this is called a nonhomogeneous Poisson process, in which case, if the variation is known, the (time) axis can be transformed to produce a homogeneous process (i.e., by squeezing and stretching the axis appropriately). This type of approach was used in Laycock *et al.*<sup>31</sup> to model the initiation of crevice corrosion of stainless steels *via* metastable pitting events in open-circuit conditions.

A standard all-purpose technique for estimating the unknown parameters in these and more extensive models is the method of maximum likelihood (ML), which directly enables the production of standard errors, confidence intervals, and prediction intervals for estimated parameters and predictions about future values for  $Y$ . An application of all these techniques in a corrosion context can be found elsewhere.<sup>32</sup>

### 2.36.2.4 Extreme Value Distributions

Extreme value (EV) distributions are typically applied in a corrosion context to maximum pit depths measured on a set of test coupons or from sampled areas on a large metal structure. They may have been recorded at one moment in time or at several distinct times, and interest may center on extrapolation in time and/or over larger areas. Relevant environmental parameters may have been measured along with the measured maxima. The models can be applied to single maxima or extended to include the largest two or largest three *et cetera* on each coupon or sampled area. An introductory text for the application of these methods can be seen elsewhere.<sup>33</sup>

Gnedenko<sup>34</sup> fully characterized the limit (implying a large amount of unrecorded data, such as smaller pits) distribution of the maximum (or minimum) as being one of three types: I, II, or III. One textbook<sup>6</sup> suggests that the maximum pit-depth is often described by the Type I distribution, although Type III with a finite upper bound has been found elsewhere.<sup>35</sup> Gnedenko's limit theorems on the maximum are analogous to the celebrated 'Central Limit theorem' on the mean. These distributions reproduce their form under maximization of further data in the same way that the Normal distribution reproduces itself under summation. The Type I distribution is more commonly known as the Gumbel or, simply, the EV distribution. The Type II is known as a Fréchet distribution, and the Type III for maxima can be described as a reversed three parameter Weibull distribution. The distribution function of the EV with location parameter  $\delta$  and scale parameter  $\alpha$  – EV( $\delta, \alpha$ ) – is

$$F(y) = \exp[-\exp[-(y - \delta)/\alpha]],$$

$$-\infty < y < \infty, \alpha > 0 \quad [14]$$

The mode is  $\delta$ , and the mean is  $\mu = \delta + \gamma\alpha$ , where  $\gamma$  is the Euler constant, 0.57721... , while the standard deviation is  $\sigma = \alpha\pi/\sqrt{6}$ .

The generalized extreme value distribution (GEV) subsumes the Type I, II, and III distributions into a single three parameter distribution – GEV( $\delta, \alpha, \kappa$ ) – with distribution function (for maxima)

$$F(y) = \exp\{-[1 - \kappa(y - \delta)/\alpha]^{1/\kappa}\},$$

$$\alpha > 0, \kappa y \leq \kappa\xi = \alpha + \kappa\delta \quad [15]$$

and shape parameter  $\kappa < 0$  for Type II with lower bound  $\xi$ ,  $\kappa > 0$  for Type III with upper bound  $\xi$ , and when the  $\kappa$  parameter reaches zero, the GEV

becomes the unbounded EV. The mapping  $y \rightarrow -y$  recovers the form for minima. The mean is

$$\mu = \delta + \frac{\alpha}{\kappa}[1 - \Gamma(1 + \kappa)]$$

$$= \xi - \frac{\alpha}{\kappa}\Gamma(1 + \kappa), \text{ provided } \kappa > -1, \quad [16]$$

and the standard deviation is

$$\sigma = \frac{\alpha}{\kappa}[\Gamma(1 + 2\kappa) - \Gamma(1 + \kappa)^2]^{1/2},$$

$$\text{provided } \kappa > -\frac{1}{2} \quad [17]$$

Note that some references use  $\xi$  or  $\gamma = -\kappa$  for the shape parameter. Most, but not all, continuous distributions have a limiting form that is a member of the GEV family. In particular, both tails of the Normal distribution (i.e., maximum or minimum values) have a limiting Type I distribution, as have maxima from a Weibull distribution, while minima from a Weibull distribution have exactly a Type III distribution.

The joint generalized extreme value (JGEV) multivariate density function for the  $r$  largest order statistics  $\mathcal{Y}_{(1)}^* > \mathcal{Y}_{(2)}^* > \dots > \mathcal{Y}_{(r)}^*$  (e.g., from a single coupon at one moment in time) is

$$f(\mathcal{Y}_{(1)}^*, \mathcal{Y}_{(2)}^*, \dots, \mathcal{Y}_{(r)}^*) = \alpha^{-r}$$

$$\exp\left\{-(1 - \kappa(\mathcal{Y}_{(r)}^* - \delta)/\alpha)^{1/\kappa} - \left(\frac{1}{\kappa} - 1\right)\right.$$

$$\left.\sum_{j=1}^r \log\left(1 - \kappa(\mathcal{Y}_{(j)}^* - \delta)/\alpha\right)\right\} \quad [18]$$

with bounds as for the GEV and a limiting form when  $\kappa = 0$ , but the joint cumulative distribution function does not have a simple closed form expression.

These distributions can be fitted to data using ML techniques. For the EV distribution, suitable starting values for iterative ML can be obtained by plotting the order statistics  $\mathcal{Y}_{(1)} \leq \mathcal{Y}_{(2)} \leq \dots \leq \mathcal{Y}_{(n)}$  against  $F^{-1}(i/(n+1) = -\ln(-\ln(i/(n+1))))$ ,  $i = 1, 2, \dots, n$ , which can be done using EV plotting paper. The intercept and slope of the line then provide estimates of  $\delta$  and  $\alpha$ , respectively, while deviations downwards from the line at the upper end may indicate a Type III distribution with  $\kappa > 0$  and hence an absolute upper bound. By extending the EV fitted line, extrapolated values for percentiles such as

$$\hat{y}_N = \hat{F}^{-1}(N/(N+1)) = \hat{\delta} - \hat{\alpha}\ln$$

$$(-\ln(N/(N+1))) \approx \hat{\delta} + \hat{\alpha}\ln(N) \quad [19]$$

can be read directly off the graph. In hydrology and meteorology, where data are typically annual maxima, ‘ $N = T$  years’ is described as ‘the return period,’ and setting  $T = 100$  years leads to the so-called ‘hundred year storm’ prediction. In corrosion, where data are more typically from sampled areas of size  $a$ , say,  $\hat{y}_N$  becomes an extrapolation over the extrapolation area  $A = Na$ . The  $N$ th return level  $\hat{y}_N$  is that value which would be exceeded, on average, once every  $N$  time or area units. Alternatively, since  $y_N$  is the maximum of a set of maxima, it will also have a distribution from the GEV family. This will be  $\text{GEV}(\delta_N, \alpha_N, \kappa)$  where

$$\delta_N = \delta + \alpha(1 - N^{-\kappa})/\kappa, \alpha_N = \alpha N^{-\kappa}$$

and bound  $\xi = \delta + \alpha/\kappa, \kappa \neq 0$ , unchanged [20]

The mean of this distribution is a best estimator for  $y_N$  in the usual mean-squared error sense

$$\begin{aligned} \mu_N &= \delta_N + \frac{\alpha_N}{\kappa} [1 - \Gamma(1 + \kappa)], \text{ provided } \kappa > -1 \\ &= \delta + \alpha(\gamma + \ln(N)) \text{ when } \kappa = 0 \\ &\rightarrow \delta + \alpha \ln(N), \text{ as seen before} \\ &\text{for the EV ‘return period’ method} \end{aligned} \quad [21]$$

When covariates, such as time, are measured along with each maximum, a regression model for the mean – and possibly the variance or scale parameter – is required. Given a covariate vector  $\mathbf{x} = (x_1, x_2, \dots, x_p)^T$  at each maximum, a multiple regression model might set  $\delta_i = \beta^T \mathbf{x}_i = \beta_1 x_{1i} + \beta_2 x_{2i} + \dots + \beta_k x_{ki}, i = 1, 2, \dots, n$  implying modeled mean

$$\begin{aligned} E[y_i | \mathbf{x}_i] &= \beta_0 + \beta^T \mathbf{x}_i \text{ with intercept} \\ \beta_0 &= \frac{\alpha}{\kappa} [1 - \Gamma(1 + \kappa)] \end{aligned} \quad [22]$$

and constant residual variance

$$\begin{aligned} \text{Var}[y_i | \mathbf{x}] &= \sigma_e^2 \\ &= (\alpha/\kappa)^2 [\Gamma(1 + 2\kappa) - \Gamma(1 + \kappa)^2] \end{aligned} \quad [23]$$

After fitting such a model using ordinary least-squares, the fitted intercept and residual variance could be equated to the above formulae and solved for  $\alpha$  and  $\kappa$ , enabling an estimate of the bound  $\xi$  to be obtained as a function of the covariates. The alternative of a constant coefficient of variance model can be achieved by additionally setting  $\alpha_i = \rho \beta^T \mathbf{x}_i$ , where  $\rho = \sigma/\mu$ , so 100 $\rho\%$  is the percentage variability in the data, independent of mean size. When the only covariate is time,  $t$ , and a fixed ‘corrosion rate’ parameter,  $\beta$ , is desired,

then we must set  $\delta_i = \beta t_i$ . Alternatively, setting  $\delta_i = \beta t_i^b$  allows for square-root, cube-root, or other nonlinear dependency on time, as referenced elsewhere in this chapter.

### 2.36.2.5 Threshold Techniques

These techniques can be applied in situations wherein we are interested in the statistical properties of extremes from a single large sample, such as feature depths from an Intelligent Pigging run or current noise measurements obtained by online corrosion monitoring.

Given a large random sample of measurements on such a  $y$  for a given threshold value  $u$ , the exceedances,  $x$ , are defined by  $x = y - u$  for  $y > u$ . It can be shown, see for example Smith and Davison,<sup>36</sup> that for sufficiently high thresholds and for a wide variety of initial distributions, the number,  $n$ , of these exceedances has asymptotically a Poisson distribution, while their sizes have a generalized pareto distribution (GPD) with CDF

$$F(x) = 1 - (1 - \kappa x/\sigma)^{1/\kappa}, x > 0 \quad [24]$$

The mean is  $\sigma/(1 + \kappa), \kappa > 1$ , and the variance is  $\sigma^2/[(1 + \kappa)^2(1 + 2\kappa)], \kappa > 1/2$ . Maxima from this distribution have a GEV distribution with shape parameter  $\kappa$ . A suitable value of the minimum threshold, above which the GPD will hold, can be found by plotting the mean exceedances in the data against the increasing threshold. This plot should eventually follow a straight line with slope  $-\kappa/(1 + \kappa)$  and intercept  $\sigma/(1 + \kappa)$ . A horizontal plot corresponds to  $\kappa = 0$  and a simple exponential distribution for this tail area distribution.

### 2.36.2.6 Wiener Process Modeling

Successive pigging runs along a corroding pipeline or successive surveys over any corroding structure will, in general, exhibit an increasing spread, as measured by range or variance,  $\sigma^2$ . Models with variance proportional to time are a consequence of incrementally additive assumptions for corrosion – which assumption is used, for example, in the theoretical ‘shot noise’ models for electrochemical noise measurements in pitting and crevice corrosion, as proposed by Cottis and other workers.<sup>37,38</sup> A statistical model incorporating linear growth in the mean and additive corrosion noise plus

instrument noise for tracked feature depths on two successive runs or surveys is

$$y_{ji} = \beta t_j + \omega_{ji} + \varepsilon_{ji}, \text{ where } \omega_{ji} \sim W(0, t_j \sigma_w^2)$$

is a Wiener additive (corrosion) noise process

and  $\varepsilon_{ji} : N(0, \sigma_M^2)$  is measurement noise;

$j = 1, 2$  runs or surveys;  $i$  = feature identifier.

[25]

A Wiener process has the simple property that its additive increments are normally distributed. It follows that the model for the corrosion increment  $y_{(2-1)i}$  is

$$y_{(2-1)i} = \beta(t_2 - t_1) + \omega_{(2-1)i} + \varepsilon_{(2-1)i}$$

$$\sim N(\beta(t_2 - t_1), (t_2 - t_1)\sigma_w^2 + 2\sigma_M^2),$$

where  $\omega_{(2-1)i} \sim N(0, (t_2 - t_1)\sigma_w^2)$  and  $\varepsilon_{(2-1)i}$

$$\sim N(0, 2\sigma_M^2); i = \text{feature identifier.} \quad [26]$$

Since we know  $(t_2 - t_1)$ , the sample mean for  $y_{(2-1)}$  will provide an estimate  $\hat{\beta} = \bar{y}_{(2-1)} / (t_2 - t_1)$ , which can then be scaled to a yearly rate if the time units are not years.

Given the sample variance  $s_{(2-1)}^2$  for  $y_{(2-1)}$ , the estimated variance for this estimated  $\beta$  will be  $\hat{\sigma}_\beta^2 = s_{(2-1)}^2 / [N(t_2 - t_1)^2]$ , which can then be used to provide a confidence bound on this mean rate. Because the sample count,  $N$ , for pigging runs and oil platform or chemical plant surveys is typically large or very large, this particular adjustment may prove minor. However, feature tracking with successive pigging runs is technically and practically difficult, and this may lead to concentration on just a few of the measured features. In particular, discarded data, here, will include features that appear in one run but not in the other. Assuming a constant probability in time for such omissions (note that dependence on size will not matter for the differenced data), discarding these data will clearly not bias the subsequent estimates, although including such discarded data in a full likelihood analysis could improve the precision of such estimates. Given an independent estimate of  $\sigma_M$  – as supplied by the manufacturer of the measuring instrument, say, and the sample variance  $s_{(2-1)}^2$  for  $y_{(2-1)}$ , we can then estimate  $\sigma_w^2$  to be equal to  $(s_{(2-1)}^2 - 2\sigma_M^2) / (t_2 - t_1)$ . Assuming the time units are years, a (two-sided) prediction interval for  $y_\delta$  – the (true, as opposed to measured) corrosion increment after 1 year – will therefore be  $y_\delta = \hat{\beta} \pm t \sqrt{(\sigma_\beta^2 + \sigma_w^2)}$ , where ‘ $t$ ’ comes from Student’s  $t$ -distribution on  $(N - 1)$  degrees of

freedom. Dropping the minus sign converts this into a one-sided (upper bound) prediction interval with an appropriately adjusted probability level. A set of  $n$  successive runs or surveys will provide a set of  $(n - 1)$  independent increments with means and variances to be pooled appropriately, which can then be used in the formulae mentioned earlier.

### 2.36.2.7 Sampling Theory and Sample Surveys

The statistical methods in sampling theory are principally designed for sampling large inhomogeneous populations of discrete items, such as motor vehicles, books in libraries, or populations of people. Two key ideas that can be useful when measuring corrosion on large structures such as an oil platform or pipeline are ‘stratification’ and ‘clustering.’ The strata of a population arise from dividing the whole population into identifiable groups such that the between-groups variability is likely to be larger than that within the groups. So elbows, joints, verticals, horizontals, and valves might form such a stratification on a large industrial structure. Clusters arise from grouping the whole of each such stratum into convenient and identifiable clumps of items for subsequent ease of sampling within each cluster. This process can be extended in a nested fashion. In a two-stage procedure, one or more clusters are chosen at random from every stratum, and then one or more items are chosen at random from each of the selected clusters. Practical introductions to these ideas, along with their theoretical justification, can be found elsewhere.<sup>39,40</sup>

### 2.36.2.8 Experimental Design

When used, the statistical principles and methods of experimental design can both help to justify the assumptions made in the standard analyses of experimental results and also improve the efficiency of the information gathering for a given amount of experimental effort. Two reference books on this subject are Cobb<sup>41</sup> and Cox and Reid.<sup>42</sup> Randomization, blocking, factorials, and fractions, Latin Squares, central composite, and optimal design are names of some of the main ideas in this area of statistics. For an illustrative example in corrosion, consider an experiment wherein metal coupons made of a particular alloy are to be corroded in a controlled environment with two flow rates F1 and F2, two temperatures T1 and T2, and two levels of acidity pH1 and pH2. In a full factorial experiment, a ‘single replicate’ would consist

of one experiment at each of the  $2 \times 2 \times 2 = 8$  combinations of the three 'factors' flow, temperature, and acidity. Repeats would consist of exposing a further set of eight coupons to the same conditions. The addition of a base position or 'central point' at F0.T0.pH0 is often useful. This method can be contrasted with the so-called one-at-a-time experimentation, wherein each factor is altered one at a time from the base position, with repeats at each such selection. This implies a basic set of  $2 + 2 + 2 = 6$  experimental combinations. For a given number of coupons used, most analyses would show that the factorial system provides a significantly more useful set of results. Alternatively, consider a situation wherein, say for financial reasons, only four of the above eight possible factorial combinations can be attempted (though, as usual, repeats might be more easily available). There are  ${}^8C_4 = 70$  possible selections of four experiments from the eight possible, of which just two form a  $2^{3-1}$  fractional factorial (which is also a simple Latin Square in this instance). The two experiments are (F1.T1.pH1, F1.T2.pH2, F2.T2.pH1, F2.T1.pH2) and its complement. These two have the unique property that all possible pairings appear. Selecting levels at random would have a chance of just 2/70 of achieving this property. With more factors or more levels, the potential gains increase markedly.

### 2.36.2.9 Bayes' Theory

The specific relevance of Bayesian methods to engineering applications is the ability to update subjective information with data for decision-making. Although the mathematical theory dates back to 1774, the numerical integration routines required to solve practical problems were not available until the 1980s. Since then, Bayesian techniques have increasingly been used in reliability and risk applications and are likely to become indispensable tools for corrosion risk management. Bolstad<sup>43</sup> is a suitable introductory text for 'Bayesian Statistics,' while Gelman *et al.*<sup>44</sup> provide the computational details necessary to implement the methods to practical problems.

#### 2.36.2.9.1 Bayes' theorem

The essential mathematical content of the theory is 'Bayes' theorem' also known as 'Bayes' rule,' which was discovered in a restricted form by the amateur mathematician the Reverend Thomas Bayes and was subsequently published posthumously in 1763.<sup>45</sup> A more

general formula first appeared in a 1774 paper by Pierre-Simon de Laplace.<sup>46</sup> In present-day notation,

$$\Pr(B|A) = \frac{\Pr(A|B)\Pr(B)}{\Pr(A)} \quad [27]$$

or, in words, the probability that  $B$  occurs given that  $A$  occurs (i.e.,  $\Pr(B|A)$ ) is equal to the probability that  $A$  occurs given that  $B$  occurs (i.e.,  $\Pr(A|B)$ ) times the probability that  $B$  occurs (i.e.,  $\Pr(B)$ ) divided by the probability that  $A$  occurs (i.e.,  $\Pr(A)$ ).

This rather simple-looking formula hides a deep mathematical subtlety that must be thoroughly understood if we are to make proper use of Bayesian methods. As a formula in probability calculus, it is mathematically rigorous, yet ever since its first enunciation, there have been divergent interpretations of its meanings, leading to intense philosophical debate and controversy in applications. The problem lies in the interpretation of 'probability,' and we must devote some time and effort to comprehending its various meanings.

#### 2.36.2.9.2 Probability

Bayes' formula can be rearranged to give the symmetrical form

$$\Pr(B|A)\Pr(A) = \Pr(A|B)\Pr(B), \quad [28]$$

where, in fact, the quantity,  $\Pr(B|A)\Pr(A)$ , is the probability that both  $A$  and  $B$  occur, denoted by  $\Pr(A \& B)$  or  $\Pr(A, B)$ .

The generic probabilities appearing in the above formulae have the following special names:

- $\Pr(A)$  – the *total probability* that  $A$  occurs
- $\Pr(B|A)$  – the *conditional probability* that  $B$  occurs given that  $A$  occurs
- $\Pr(A \& B)$  – the *joint probability* that  $A$  and  $B$  occur

In 'frequentist' statistics, such as that presented in previous sections, these probabilities are all interpreted as long-run frequencies that occur in repeated sampling. Thus, the probability that a coin lands heads is expressed as  $\Pr(C=b) = 1/2$ , with the informal interpretation that in a 100 tosses of the coin, the frequency of heads will be 'approximately' 50.

The alternative, 'Bayesian,' interpretation is that probabilities can express degrees of belief. Thus,  $\Pr(C=b) = 1/2$ , quantifies one's current belief that the coin is fair – *a statement that can be made even without any data!* Note, however, that an *Empirical Bayesian* would be allowed to use previously collected data to calculate a direct estimate of such a probability. The chief use of Bayes' Theorem in the context of *Bayesian*

*methods* is to revise such beliefs given data. We will illustrate this procedure, assuming that the coin has landed tails-up in a single toss; that is, the event  $C = t$  has occurred.

### 2.36.2.9.3 Prior and posterior probabilities

The probability of tails is given by the Bernoulli data model,  $\Pr(C = t|\Theta = \theta) = 1 - \theta$ , where  $\Theta$  is the probability of heads. Notice that we use a capital Greek letter for the Bernoulli parameter, which is, according to the Bayesian paradigm, a *random variable* and not a *fixed unknown value*. This is an essential point of difference between Bayesian and frequentist data modeling. Most statisticians currently use both methods according to convenience, but *true Bayesians* will never use frequentist methods.

To avoid unnecessary technical details, we assume that it is known that  $\Theta$  has only two possible values  $\theta_1$  and  $\theta_2$ , which are known *a priori*. Then, applying Bayes' rule,

$$\begin{aligned}\Pr(\Theta = \theta|C = t) &= \frac{\Pr(C = t|\Theta = \theta)\Pr(\Theta = \theta)}{\Pr(C = t)} \\ &= \frac{(1 - \theta)}{\Pr(C = t)}\Pr(\Theta = \theta)\end{aligned}\quad [29]$$

To calculate the probability in the denominator, we use *the total probability formula*

$$\begin{aligned}\Pr(C = t) &= \Pr(C = t|\Theta = \theta_1)\Pr(\Theta = \theta_1) \\ &\quad + \Pr(C = t|\Theta = \theta_2)\Pr(\Theta = \theta_2)\end{aligned}\quad [30]$$

which gives

$$\begin{aligned}\Pr(\Theta = \theta|C = t) &= \frac{(1 - \theta)}{(1 - \theta_1)\Pr(\Theta = \theta_1) + (1 - \theta_2)\Pr(\Theta = \theta_2)}\Pr(\Theta = \theta)\end{aligned}\quad [31]$$

In Bayesian statistics, the probability  $\Pr(\Theta = \theta)$  is known as the *prior probability* and  $\Pr(\Theta = \theta|C = t)$  is the *posterior probability* (having observed tails). Many of the problems that arise applying Bayes' rule can be traced to inappropriate specification of the prior. The key point to note here is that it cannot be specified independently of the data model, that is, the Bernoulli model, because in using the total probability formula, it must be true that

$$\Pr(\Theta = \theta_1) + \Pr(\Theta = \theta_2) = 1 \quad [32]$$

Hence, the prior itself cannot be entirely subjective nor can it be an arbitrary quantification of degrees of belief as some Bayesian analysts insist.

### 2.36.2.9.4 Specifying the prior

We are now faced with the problem of specifying the prior, since, evidently, it cannot be arbitrary. Laplace's own prescription for the prior – now known as an *uninformative prior* – has  $\Pr(\Theta = \theta_1) = \Pr(\Theta = \theta_2) = 1/2$ , giving the posterior

$$\Pr(\Theta = \theta|C = t) = \frac{1 - \theta}{2 - \theta_1 - \theta_2} \quad [33]$$

and the *prior predictive probability*

$$\begin{aligned}\Pr(C = b) &= \Pr(C = b|\Theta = \theta_1)\Pr(\Theta = \theta_1) \\ &\quad + \Pr(C = b|\Theta = \theta_2)\Pr(\Theta = \theta_2) \\ &= (\theta_1 + \theta_2)/2\end{aligned}\quad [34]$$

In the special case that  $\theta_1 + \theta_2 = 1$ , the uninformative prior also gives  $\Pr(C = b) = 1/2$ , and is therefore in accord with our prior belief in a fair coin. However, in all other cases, the uninformative prior gives  $\Pr(C = b) \neq 1/2$ .

An alternative to the uninformative prior is to use a customized prior that matches both the total probability constraint and our prior predictive constraint. Effectively, with  $\Pr(\Theta = \theta_1) = p$ , we must take

$$\theta_1 p + \theta_2 (1 - p) = 1/2 \quad [35]$$

and hence

$$\begin{aligned}\Pr(\Theta = \theta_1) &= \\ p &= \begin{cases} 1/2 & \theta_1 = \theta_2 \\ (1/2 - \theta_2)/(\theta_1 - \theta_2) & \theta_1 \neq \theta_2 \end{cases}\end{aligned}\quad [36]$$

Such a prior is consistent with the data model and belief in a fair coin even when, *a priori*, it is known that neither  $\theta_1$  nor  $\theta_2$  is equal to  $1/2$ . This is because the parameter  $\Theta$  in the Bernoulli data model is a *random variable* and *not some fixed unknown value*.

Now, however, there is a degenerate case in which one, but not both, of  $\theta_1$  or  $\theta_2$  is equal to  $1/2$ . In this case, the prior becomes  $\Pr(\Theta = \theta) = \delta(\theta - 1/2)$  ( $\delta$  is the delta function:  $\delta(0) = 1$  and  $\delta(x) = 0$  for  $x \neq 0$ ). The prior no longer has a nonzero value on all possible values, and, therefore, there is no possibility of updating the prior, since Bayes' rule gives  $\Pr(\Theta = \theta|C = t) = \Pr(\Theta = \theta|C = b) = \Pr(\Theta = \theta)$ .

This phenomenon has been called the 'zero preservation problem.' It actually points to an inconsistency between our prior belief and the data model and requires revision of one or more of our models. Clearly, the quantification of even the most uncontroversial beliefs – here, simply that a coin is fair – is

fraught with technicalities, and it is no wonder that Bayesian methods are often controversial.

### 2.36.2.9.5 Robust Bayes

The coin example reveals how, in the Bayesian paradigm, consistency between prior beliefs and a data model is obtained by randomization over the parameters using the prior. At the limits of this randomization process are degenerate cases in which the prior has zero probability, and there is no possibility of updating prior beliefs by data. Although Bayes' rule is still formally applicable, there is really too great an inconsistency to proceed with the analysis, without a major revision of either our beliefs or the data model.

These issues, especially the 'zero preservation problem,' are especially relevant in applying Bayesian methods to engineering risk, where risks can be seriously underestimated. There is now increasing recognition by practitioners that some form of sensitivity analysis is required to augment the standard Bayesian analysis.

Currently under development are 'robust Bayes' methods that address many of the problems identified. The most promising methods employ *classes of priors*, which are appealing from a mathematical viewpoint, because Bayes' rule maps classes of priors to *multivalued predictive probabilities*. Thus, in the coin example, a prior class such as

$$\{\delta(\theta - \theta_1), \delta(\theta - \theta_2), [\delta(\theta - \theta_1) + \delta(\theta - \theta_2)]/2\} \quad [37]$$

yields the multivalued prior predictive probability

$$\Pr(C = b) \in \{\theta_1, \theta_2, (\theta_1 + \theta_2)/2\} \quad [38]$$

Such multivalued probabilities have a clear interpretation in terms of prior belief – here simply, that the probability of heads takes on one of the three values.

## 2.36.3 Corrosion Science

This section demonstrates the application of some of the above techniques to the analysis of experimental data, primarily from laboratory studies.

### 2.36.3.1 Pitting Potentials and Induction Times

One common method for the experimental study of pitting corrosion is the measurement of 'pitting potentials.' Typically, multiple repeat experiments are carried out for each given set of experimental conditions, using a freshly prepared sample for each

test. This produces several measurements of the pitting potential for the given set of conditions, and these measurements will be spread over a range of potentials that is much wider than that of the inherent measurement error and can be attributed to the mechanistic details of the pit initiation process. Following Shibata and Takeyama,<sup>5</sup> such data are often presented as sample cumulative probability distribution functions, as shown in Figure 5.

Similarly, another common experiment is to measure the 'induction time' before stable pitting is observed on a given sample. Results of these experiments on multiple samples can be presented as the (estimated) survival probability function,  $S(t)$ , by plotting the  $i$ th-order statistic against  $1 - i/(n + 1)$ , as described in the basic terminology and methods section. Further examples and discussion on these methods can be found elsewhere.<sup>5,7,14</sup>

### 2.36.3.2 Coupon Testing

Corrosion coupons are often exposed in a test environment for significant periods of time and then examined to enable the determination of their corrosion rate. Usually, the examination consists of removing solid corrosion products and then measuring both the depth of any pits and the total weight lost from the coupon during the exposure. Sometimes, electrochemical methods may also be used to obtain corrosion rate information at certain times during the exposures. This section describes some examples of statistical approaches to the analysis of the resulting data.

**Figure 5** Typical results from potentiodynamic pitting potential measurements for 304 stainless steel with a 220 grit surface finish, in sodium chloride solutions at 60 °C. Each datapoint is the pitting potential of an individual test on a freshly prepared sample.

### 2.36.3.2.1 Straight-line regression analysis of weight loss data

Figure 6 shows the metal loss from carbon steel coupons exposed at two statistically similar sites along the River Thames over a period of 5 years.<sup>47</sup> The metal loss (mm) was calculated from the weight loss by assuming one-side uniform corrosion and applying Faraday's Second Law, and the slope of the 'best fit' line gives an estimate of the 'corrosion rate' (mm year<sup>-1</sup>) over the measurement period.

Although a formal approach to corrosion might suggest omitting the intercept,  $a$ , to give a simple regression through the origin, that is  $y = bx$ , it is rarely sensible to do this in practice for the whole of a data set unless an appropriate significance test on  $a$  suggests that the intercept can be safely omitted, even though  $a$  may have no metallurgical validity at time zero. By forcing  $y$  to be zero at time zero, it may extend the formal range of validity of the model, but it will then almost certainly predict a higher (possibly much higher) corrosion rate, and it is the validity of the model for extrapolation into the future, not the past, which is important in practice.

In this case, the calculation of a prediction interval is also appropriate. This has the form

$$y_x = \hat{y}_x \pm t\hat{\sigma} \sqrt{\left(1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{\sum(x_i - \bar{x})^2}\right)} \quad [39]$$

for a future observation on  $y$  at  $x$ , with  $t$  selected appropriately from  $t$ -tables with  $(n - 2)$  degrees of

freedom. A confidence interval about the line (which omits the '1' inside the bracket above – as this term relates not to the line itself, but to future noise in the observations as they appear about the line) and the prediction interval for future observations are demonstrated in Figure 6.

### 2.36.3.2.2 Extreme value analysis of pit depth measurements

Figure 7 shows the maximum pit depth as a function of immersion time for 316L stainless steel coupons in a 10% ferric chloride solution at 50 °C, as reported by Pierpoline *et al.*<sup>48</sup> Laycock *et al.*<sup>32</sup> have fitted to this data a constant coefficient of variance model with nonlinear time dependence, using ML. This had location parameter  $\delta_i = \beta t_i^b$  and scale parameter  $\alpha_i = \rho \beta t_i^b$  (where  $\rho = \sigma/\mu$ ), and produced the following parameter estimates (with associated standard errors in brackets)

$$\begin{aligned} \tilde{\alpha} &= 1.004(\pm 0.317), \tilde{\delta} = 6.322(\pm 1.721), \\ \tilde{\kappa} &= 0.401(\pm 0.162), b = 0.376(\pm 0.047) \end{aligned} \quad [40]$$

This implies the following formula for the extrapolated mean for maxima as a function of extrapolation area  $A$  in square inches and time  $t$  in days

$$\begin{aligned} \tilde{\mu} &= (29.16 - 14.404/A^{0.401})t^{0.376} \rightarrow \\ 29.16t^{0.376} &= \xi t^{0.376} \text{ for large } A \end{aligned} \quad [41]$$

When the two or three largest (etc.) maxima are collected at each location, this can afford greater

**Figure 6** Corrosion loss from carbon steel coupons exposed in the River Thames for 5 years,<sup>47</sup> with the best-fit line obtained by straight-line regression and extrapolated for a further 5 years. Also, shown are the 95% confidence bounds for the fitted line, and the 95% prediction interval for future 'corrosion loss.'

precision for the same estimated parameters, as demonstrated for the earlier data.<sup>49</sup>

Another example is provided by a set of 1800 maximum pit depths extracted from  $8 \times 8$  grids over experimental coupons of a corrosion-resistant alloy subjected to a complex cyclic testing regime, involving hold periods at 350 °C (for between 1 and 23 h), with and without exposure to salt, for total test durations of 1 year. The statistical package Genstat was used to prepare an analysis of variance table for the data, with the results shown in [Table 1](#).

Inspection of a half-normal plot for the residuals showed good linearity, suggesting that the standard model assumptions, for this particular analysis, were sound. It can be seen that the variation of maximum pit depths between days of exposure (3, 4, or 11, treated as a factor with three levels) and temperature cycles

(either 1 or 23 h at 350 °C) and salt treatments (Yes or No) was highly significant ( $P < 0.001$ ), but the other two factors (salt replenishment and measurement position) were definitely nonsignificant ( $P > 0.5$ ) although not so small as to cast doubt on the validity of the model or data. Therefore, four experimental conditions, defined by the two temperature cycle schemes and exposure to or not to salt, were found to give statistically different results in terms of maximum pit depths, though no detectable growth of pits could be found for the cycle with 23 h at 350 °C and no salt exposure. Hence, the Fortran program described in Laycock *et al.*<sup>32</sup> was used to fit four-parameter GEV distributions to the three sets of data, which had significant upward time trends. [Figure 8](#) shows a plot against time of one of these fitted GEV mean functions, which were all Type III, for a selection of extrapolated

**Figure 7** Maximum pit depth as a function of immersion time for 316L stainless steel coupons in a 10% ferric chloride solution at 50 °C. Reproduced from Pierpoline, R.; White, R. J.; Wrong, C.; Cornwell, L.; Griffin, R. In *NACE-9: Advances in Localised Corrosion*; Isaacs, H., Bertocci, U., Kruger, J., Smialowska, S., Eds.; NACE: Houston, TX, 1990; pp 123–126.

**Table 1** Analysis of variance for pit depth data from coupons of a corrosion-resistant alloy subjected to a complex cyclic testing regime

Source of variation	Degrees of freedom	Sum-of-squares	Mean-square	Variance-ratio	F dn probability
Cycles(2)	1	79 644.4	79 644.4	548.74	<.001
Days(3)	2	19 183.6	9 591.8	66.09	<.001
Salt(Y/N)	1	10 339.5	10 339.5	71.24	<.001
Replication	1	0.1	0.1	0.00	0.975
Position	24	2 666.2	111.1	0.77	0.784
Residual	1770	256 898.0	145.1	–	–
Total	1799	368 757.5	–	–	–

1800 maximum pit depths were extracted as internal  $5 \times 5$  grids (to remove edge effects) from  $8 \times 8$  grids over experimental coupons. The statistical package Genstat was used to prepare this table.

**Figure 8** A Fortran program<sup>32</sup> was used to fit four-parameter GEV distributions to pit depth data from cyclic testing of corrosion-resistant alloy coupons. This figure shows a plot against time of one of these fitted GEV mean functions for a selection of exposure areas.

exposure areas related to operational requirements for this alloy, which was to be used inside jet engines operating in a marine environment.

### 2.36.3.2.3 Response surface regression analysis of LPRM data

Sometimes, experiments are carried out to determine the influence of various parameters (such as alloy composition) on the corrosion rate in a given environment. In one such set of experiments, linear polarization resistance measurements (LPRM) were used to measure corrosion rates for a selection of different carbon steels in a concentrated HF environment. The steels were selected because they had small differences in residual element (nickel, chromium, copper) and carbon content, and it was suspected that such variations were responsible for unexpected failures due to corrosion in HF alkylation plants. To determine the optimum steel composition for corrosion resistance in this environment, the data were analyzed using response surface regression. The most popular version of this is the bivariate second order model:

$$y_i = \beta_{00} + \beta_{10}x_{1i} + \beta_{01}x_{2i} + \beta_{20}x_{1i}^2 + \beta_{02}x_{2i}^2 + \beta_{11}x_{1i}x_{2i} + e_i \quad (i = 1, \dots, n), \quad [42]$$

which can be described as the *quadratic* version of *bivariate linear regression*, and it represents a smooth hill, or valley, or saddle-point in the response surface.

The general  $n$ th-order,  $k$ -variate, model has the form

$$y_i = \sum_{0 \leq i_1 + i_2 + \dots + i_k \leq t} \beta_{i_1 + i_2 + \dots + i_k} x_{1i}^{i_1} x_{2i}^{i_2} \dots x_{ki}^{i_k} + e_i \quad (i = 1, \dots, n) \quad [43]$$

This model has  $k$  *genuine* variables, the rest being *carrier* variates.

The fitted model was a second-order response surface for LPRM regressed on carbon, chromium, copper, and nickel content, based on 45 determinations of LPRM. This model gave a good fit to the data, with a squared multiple correlation coefficient of  $\sim 80\%$  and 30 degrees of freedom for the residual. A contour plot for the raw data is shown in [Figure 9\(a\)](#), while the corresponding contour plot for the fitted model but controlled for the hidden variates (nickel and copper at their median values) is shown in [Figure 9\(b\)](#). From this saddle-point figure, the qualitative conclusions for this application were that when copper and nickel are at their median levels (0.06% and 0.04%, respectively), a decreasing carbon content is good for corrosion resistance, provided chromium is low, while an increasing carbon content will be good when chromium is high. This analysis supported a recommendation for new guidelines on the residual element and carbon content of steels for concentrated HF service.

**Figure 9** LPRM data for carbon steels of different alloy content in deaerated 60% HF (by volume) at 71 °C, with 5 ppm of predissolved iron. The fitted model is a second-order response surface regressed on carbon, chromium, copper, and nickel content, based on 45 determinations of LPRM. A contour plot for the raw data is shown in (a), while the corresponding contour plot for the fitted model but controlled for the hidden variates (nickel and copper at their median values) is shown in (b). Data produced in a multiclient project at CAPCIS Ltd, Manchester, UK.

### 2.36.3.3 Crack Depth Modeling

Cracks in engineered structures, whether they are caused by (corrosion) fatigue or stress-corrosion cracking, can be considered, in general, as defects, which initiate and 'grow' according to some random mechanism. Hence, there is much scope for modeling. There is, of course, an extensive literature on crack growth, and, in particular, fracture mechanics has been extensively used to study the principle and nature of fatigue crack growth. Many authors present purely theoretical considerations in an attempt to provide a model to predict crack growth, and such methods have been reviewed.<sup>50,51</sup> Dolinski<sup>52</sup> is skeptical as to whether theoretical considerations alone can provide an adequate model for prediction. On the other hand, when data are presented, they are often experimental in nature,<sup>53</sup> from which it is extremely difficult to infer useful practical models for the prediction of crack growth in real complex systems. For this reason, an empirical model, which makes reasonable assumptions, and which can be evaluated or fitted using data on the nature and extent of cracks observed at inspection may be more useful in practice. This empirical approach will suppose that the physical properties of the system, such as loading history and material characteristics, are inherent in the field data and also suppose that data are available in sufficient quantity and in a form that allows the fitting of a statistical model. This model can then be used to predict fatigue crack growth and to investigate the consequences of various inspection policies. This philosophical contrast between a physical model and an empirical one based on the observation of

large scale effects is not uncommon and not easily resolved. Although the model in this section is not based strictly on fracture mechanics, the approach and the assumptions made are simple, and the approach taken is a practical one.

#### 2.36.3.3.1 Two-stage modeling of crack growth

Detailed models of crack growth will consider crack development in stages. Suppose a crack initiates according to one random process, and subsequent to initiation, it grows according to another random process independently of the initiation process. Given a simple model for each stage, the distribution of crack depths at some time  $T$  can be formulated. The simplest model that can capture the randomness of the initiation process is the homogeneous Poisson process.<sup>54</sup> This supposes that cracks initiate purely at random but at an average rate of  $\lambda$  crack initiations per unit of time. Then, the number of crack initiation events in the time period  $[0, T]$ ,  $N_T$ , will be Poisson distributed with mean  $\lambda T$ , that is,  $E(N_T) = \lambda T$  and  $\Pr(N_T = n) = e^{-\lambda T} (\lambda T)^n / n!$ .

Next, let the distribution of crack depth for a crack that has been growing for some time  $\tau$  be  $G(z; \tau) - G$ , which will be specified later. For now, put simply, not all cracks that have been growing for the same time would be expected to be of the same size – some will propagate more quickly than others. Thus, the depth of a crack  $Z$  that has been growing for a particular time will be a random variable, and this random variable will have distribution  $G$ .

Suppose a structure or an area on a structure is inspected for cracks at some time  $T$ , and a number of

cracks are observed. If any of these cracks is selected at random (with no size-related selection bias), then it is a property of the Poisson process of initiation events that the time of initiation of the crack is uniformly distributed over the interval  $[0, T]$  – that is, the crack could have initiated in any equal interval of time within  $[0, T]$  with equal probability. This can be thought of as the defining property of the Poisson process and one that characterizes events that occur ‘purely at random.’ With inspection carried out at time  $T$ , conditional on initiation of a crack at time  $x$ , the distribution of crack depth at time  $T$  will be  $G_T(z; T - x)$ . However, we do not observe  $x$ , and, therefore, predictions have to be made unconditionally. To do this, we appeal to the law of total probability so that the unconditional distribution of the crack depth at time  $T$  (with no regard to the initiation time),  $F_T(z)$ , is

$$\begin{aligned} F_T(z) &= \int_0^T \Pr(Z_T \leq z | x = x) f(x) dx \\ &= \frac{1}{T} \int_0^T G_T(z; T - x) dx, \end{aligned} \quad [44]$$

where  $f$  is the probability density function of the initiation time. This expression is interpreted as follows: the distribution of the depth  $Z$  is a weighted average of the distribution of depth, given the initiation time with weights given by the probabilities of particular initiation times. We have already stated that for the Poisson process, these initiation times are uniformly distributed on  $[0, T]$  so that  $f(x) = 1/T$ .

For  $n$  crack depths  $z_1, \dots, z_n$  observed at time  $T$ , the log-likelihood function is given by

$$\sum_{i=1}^n \log \left[ \frac{d}{dz} \left\{ \int_0^T G_T(z_i; T - x) dx \right\} \right] \quad [45]$$

From this, we can estimate the parameters of  $G$  and  $F$  by implication, and make predictions about  $Z_t$  for  $t > T$ .

It may be natural to focus on the maximum crack depth. Only the maximum crack depth may be recorded. In this case, given  $n$  crack initiations in the interval  $[0, T]$ , the distribution function of the maximum crack depth is  $F_{\max, T}(z | N_T = n) = \{F_T(z)\}^n$ , given the assumption that the  $n$  crack depths are independent and identically distributed. If, in general, the number of cracks at a location at an inspection is unknown, it follows, arguing unconditionally on  $N_t$ , that the distribution function of the maximum crack depth is given by  $F_{\max, T}(z) = \sum_{n=0}^{\infty} \{F_T(z)\}^n \Pr(N_t = n)$ , and the likelihood for

an observed maximum crack depth  $z_{(1)}$  is  $\log \left[ \frac{d}{dz} F_{\max, T}(z_{(1)}) \right]$  if  $z_{(1)} > 0$  and  $\log[\Pr(N_t = 0)] = -\lambda T$  if  $z_{(1)} = 0$  (i.e., if no cracks have initiated).

With  $F_T(z)$  given by eqn [44], it then follows that

$$\begin{aligned} F_{\max, T}(z) &= \sum_{n=0}^{\infty} \left\{ \frac{1}{T} \int_0^T G_T(z; T - x) dx \right\}^n e^{-\lambda T} (\lambda T)^n / n! \\ &= \exp \left\{ -\lambda \int_0^T 1 - G_T(z; T - x) dx \right\} \end{aligned} \quad [46]$$

As to the form of the distribution function for  $G_T(z; T - x)$ , for simplicity, the two-parameter Weibull distribution is recommended. This distribution is widely used in reliability for modeling failure times.<sup>55</sup> Taking the scale parameter  $\alpha$  of the Weibull to be a power function of the ‘growing time,’  $\tau = T - x$ ,  $G$  becomes

$$G_T(z; \tau) = 1 - \exp[-\{z/(\alpha_0 \tau^\gamma)\}^\beta], \quad [47]$$

where  $\beta$  is the shape parameter. This implies that the mean depth grows according to  $\mu = \alpha_0 \Gamma(1 + 1/\beta) \tau^\gamma$ , and where  $\Gamma(\cdot)$  is the gamma function. This power law function for the scale parameter, while having no immediate physical justification, provides, along with the Weibull distribution, a flexible family of growth laws and also implies power law growth in the mean. The implied distribution of the maximum crack depth is then

$$\begin{aligned} F_{\max, T}(z; \lambda, \alpha_0, \beta, \gamma) \\ = \exp \left[ -\lambda \int_0^T \exp \left[ -\left\{ \frac{z}{\alpha_0 (T - x)^\gamma} \right\}^\beta \right] dx \right] \end{aligned} \quad [48]$$

Extrapolation in space and time now proceeds as follows. Suppose the estimation of the maximum is carried out using maxima from sampled regions of area  $A$  at time  $T$ , if we wish to determine the distribution of the maximum over an area  $a > A$  at time  $t > T$ , then it is required to scale up the initiation rate  $\lambda$  to  $\lambda(a/A)$ , and, therefore, the distribution of the maximum over an area  $a$  at time  $t$  is then

$$\begin{aligned} F_{\max, t, a}(z; \lambda, \alpha_0, \beta, \gamma) \\ = \exp \left[ -\lambda \left( \frac{a}{A} \right) \int_0^t \exp \left[ -\left\{ \frac{z}{\alpha_0 (t - x)^\gamma} \right\}^\beta \right] dx \right]. \end{aligned} \quad [49]$$

If  $X$  is the time for the maximum crack depth to reach some critical level,  $z_f$ , then the expected value of  $X$  can be determined from this distribution, since  $\Pr(X > t) = \Pr(Z_{\max, t, a} < z_f)$  and  $E(X) = \int_0^\infty \Pr(X > t) dt$ .

### 2.36.4 Corrosion Engineering

Statistical data analysis techniques have long been used in the assessment of corrosion damage to industrial plant. Such techniques can be applied to *condition assessment*, wherein there typically are concerns about the influence of measurement error and the extrapolation of sample inspection results to uninspected areas; and *life prediction*, wherein the goal is to determine the remaining life of the equipment.

#### 2.36.4.1 Sample Inspection of Heat Exchanger Tubes

Heat exchanger tubes are often inspected using non-destructive testing (NDT) methods – such as IRIS (internal rotary inspection system) or LOTIS (laser optical tube inspection system) – and the results are typically reported in terms of the maximum pit depth in each inspected tube. However, in many such cases, no more than 10 or 20% of the tubes are tested, at least initially, and the sample data must be used to estimate the overall condition of the tube bundle. The hypergeometric distribution – as described in the introductory section – can be applied here to determine the required level of inspection for a given detection requirement.

ASTM G46<sup>10</sup> describes a procedure based on the Type-I EV (Gumbel) distribution for extrapolating maximum pit depths over areas larger than the inspected area, and this technique is described in the following example. A carbon steel ammonia condenser with cooling water on the tube-side was inspected after ~2 years service. The exchanger contained 773 nominally identical tubes, of which 54 were inspected, and the maximum measured pit depth from each inspected tube was recorded. The method described in G46 was

then applied to this dataset, as shown in [Figure 10](#). In this case, the extent of inspection was ~7%, and the maximum measured pit depth was 0.99 mm, while the maximum predicted pit depth was 1.32 mm.

The previous example provides no validation that the analysis has produced an accurate estimate of the condition for the uninspected tubes. However, the next example concerns another exchanger with cooling water on the tube side, in which 357 out of 410 tubes were inspected (with the remaining 53 tubes being uninspectable due to obstructions). To assess the accuracy of the GEV analysis technique, the full dataset was randomly sampled to create simulated inspection datasets of different sizes from 5 to 100 tubes. For each of these simulated datasets, the GEV technique was used to estimate the maximum pit depth in the entire 410 tube bundle, with 95% confidence limits also determined for each prediction. As shown in [Figure 11](#), for sample sizes over ~50 tubes (or ~25% inspection), the estimated maximum pit depth is both quite stable and in excellent agreement with the maximum measured pit depth from all the inspected tubes.

In the latter example, it is also instructive to consider the measurement error. For the NDT technique used in this case, the stated accuracy on clean tubes was  $\pm 0.05$  mm, but this varies for other inspection methods. For a sample size of 10% (40 tubes), [Figure 12](#) shows the impact of taking this effect into account. The ML estimates for the Gumbel parameters were obtained using the Xtremes software of Reiss and Thomas.<sup>56</sup> To allow for small sample calculations, we use the parametric bootstrap method to obtain standard errors and confidence limits.<sup>57</sup> The bootstrap method is implemented in the Xtremes software. Therefore, all we need to do is adjust the ML estimates to allow for the measurement error.

**Figure 10** ASTM G46 extrapolation method for maximum pit depth in an ammonia condenser with 54 tubes inspected out of 773 in total. The return period is 773, and the maximum expected pit depth is 1.32 mm.

**Figure 11** For a cooler with pitting corrosion on the internal surface of the tubes, this figure compares the maximum measured pit depth in samples of varying size (up to 100 sampled tubes); the calculated maximum pit depth based on GEV analysis of the given sample size; and the maximum measured pit depth in the 357 inspected tubes from the 410 tube bundle (1.85 mm).

**Figure 12** For a cooler with pitting corrosion on the internal surface of the tubes. As a function of the assumed inherent measurement error, this figure compares; the maximum calculated pit depth based on inspection of a random 10% sample of the tubes; and the maximum measured pit depth in the 357 inspected tubes from the 410 tube bundle (1.85 mm).

In the special case that the measurement error is uniform, we use the following method.

The (ideal) genesis of the Gumbel is as follows:

1. The distribution of deep pits follows an exponential distribution,  $1 - \exp(-(x - \theta)/\sigma)$ .
2. The number of deep pits follows a Poisson distribution with mean  $\lambda$ .

Then, the distribution of the maximum pit depth follows the Gumbel distribution,  $\exp[-\exp\{-(x - \theta)/\sigma + \ln(\lambda)\}]$ , which has mode  $\theta + \sigma \ln(\lambda)$  and scale  $\sigma$ .

If, in fact, the pits are measured with uniform error between  $-R$  and  $R$ , then the distribution of measured depths  $x$  is exponential with distribution function  $1 - \exp[-(x - \theta - \varepsilon)/\sigma]$ , where

$$\varepsilon = \sigma \ln \left[ \frac{\sinh(R/\sigma)}{R/\sigma} \right] \quad [50]$$

The resulting distribution of the maximum measured pit follows the Gumbel distribution,  $\exp[-\exp\{-(x - \theta - \varepsilon)/\sigma + \ln(\lambda)\}]$ , which has mode  $\theta + \varepsilon$

+  $\sigma \ln(\lambda)$  and scale  $\sigma$ . Therefore, the effect of the measurement error is to increase the mode by an amount  $\varepsilon$ . Hence, given the ML estimates,  $\hat{\mu}$  and  $\hat{\sigma}$ , the appropriate adjustment for uniform error is to *reduce* the mode by an amount

$$\hat{\varepsilon} = \hat{\sigma} \ln \left[ \frac{\sinh(R/\hat{\sigma})}{R/\hat{\sigma}} \right] \quad [51]$$

while leaving the scale estimate as  $\hat{\sigma}$ . The usual parametric bootstrap can now be applied with the adjusted parameters to obtain the required standard errors and confidence limits. Further discussion on these techniques can be found elsewhere.<sup>58</sup>

#### 2.36.4.2 Thickness Measurement Locations

Corrosion engineers are frequently faced with the situation wherein they have inspection data showing the change in wall thickness (or increase in pit depth) at certain locations on a given piece of equipment

over several months or years, and are now being asked to predict the remaining useful life of this equipment. Here, we ignore the various possible different definitions for 'end-of-useful-life' and assume that there is a defined minimum allowable wall thickness, and that reaching this thickness at any one location constitutes the end-of-life for the given piece of equipment. In-service inspection codes<sup>59,60</sup> describe simple ways of calculating corrosion rates for a single thickness measurement location (TML); for example, the long-term corrosion rate is determined from the wall loss between the first measurement and the most recent measurement, while the short-term corrosion rate is obtained using only the two most recent measurements. However, there are also several different statistical approaches to this problem.

#### 2.36.4.2.1 Straight-line regression

Figure 13 shows the wall thickness data obtained by ultrasonic testing at one particular location on a wet gas flowline over a period of several years.

In this case, the observed erosion-corrosion damage was restricted to the outside of a bend, and the inspections always covered 100% of the damaged area such that there is no concern here about extrapolation of the results to other locations. As in the

earlier examples concerning coupon testing data, the slope of this 'best fit' line gives an estimate of the 'corrosion rate' over the measurement period, and a confidence interval about the line and the prediction interval for future observations are also shown. The corresponding graphic produced for these data by the Shell inspection design analysis and plotting (S-IDAP) package<sup>61</sup> is presented in Figure 14, where it is seen to present much the same predictions out to the same time point in 2008.

#### 2.36.4.2.2 Extreme value analysis

In this example, ultrasonic testing has been used to map the extent of internal corrosion damage to a carbon steel Benfield process vessel.<sup>62</sup> Inspections were carried out ~1 year apart, the measurements made using continuous scans of 50 mm × 50 mm grids and the minimum measured wall thickness being reported for each grid. For the worst case (thinnest) locations at the first inspection, the maximum measured wall loss between the two inspections was 0.6 mm, but, on average, there was negligible change (Table 2). It might be assumed, therefore, that the apparent differences between results at specific TMLs are all due to the measurement error (which has a mean of zero). However, for 8 of the 11

**Figure 13** Minimum wall thickness data from ultrasonic testing measurements on the outside of a bend in an offshore gas flowline, with confidence and prediction intervals around the best fitting line.

**Figure 14** The same measurement data as in Figure 13, with the extrapolation in time carried out using the S-IDAP package described by Hoeve *et al.*<sup>61</sup>

**Table 2** Ultrasonic testing results from inspection of a Benfield Process vessel at several thickness measurement locations in 2001 and 2002<sup>62</sup>

The selected locations are those where the minimum wall thicknesses were found in 2001. Note that negative values indicate an apparent increase in wall thickness.

circumferential rows making up the inspected area, the minimum measured thickness was found in a different grid in the two inspections. This happens partly because of inherent measurement errors and partly because the highest corrosion rates are not necessarily experienced at the same locations at all times.

An alternative approach to this problem again takes advantage of extreme value analysis methods. In Figure 15, the maximum wall loss in each circumferential row is plotted for each inspection time. This is done in such a way that data conforming to a Type-I EV distribution would fall along a straight line. Hence, it is clear that the data from each inspection follow a Type-I EV distribution, but the entire distribution has shifted to higher wall loss values over time, as might reasonably be expected in a vessel suffering from corrosion. The corresponding corrosion rate can be calculated from the change in the Gumbel mode (assuming the same scale). Thus, we consider  $x \sim \text{EV}(\mu, \sigma)$  for the wall loss data from August 2001 and  $x \sim \text{EV}(\mu + \Delta, \sigma)$  for the data from November 2002. As the data are based on minima from different locations, we can assume that the wall loss results are statistically independent, yielding two independent samples, each of size 11. Using the ML estimation procedure, we obtain the parameter estimates  $\hat{\mu} = 5.05$ ,  $\hat{\sigma} = 0.36$ , and  $\hat{\Delta} = 0.43$ . In general, ML estimates are biased in small samples. To estimate the bias-corrected estimate and its standard error, we use the two-sample *jackknife* procedure, which gives  $\hat{\Delta} = 0.46$  with

**Figure 15** EV analysis of minimum wall thickness data from surveys of a Benfield process vessel in August 2001 and November 2002. The progression of the distribution from left to right shows the rate at which the minimum wall thickness is decreasing, which is a practical definition of the corrosion rate. Reproduced from Wilson, P. T.; Krouse, D. P.; Moss, C. J. Proceedings of Corrosion Control and NDT; ACA, Melbourne, Australia, 23–26 November 2003; ACA: Melbourne, 2003; Paper no. 45.

standard error 0.22. Note that the *large sample* standard error for the ML estimate of the mode is  $\sigma\sqrt{\frac{1.11}{n}}$ .

In the present case, this is estimated by  $0.36\sqrt{1.11/11} = 0.114$ . Hence, the standard error for the difference of two independent ML estimates is  $0.114\sqrt{2} = 0.16$ , which is, as expected, somewhat less than that obtained using the jackknife procedure.<sup>57</sup> Thus, we conclude that a wall loss of  $0.46 \pm 0.22$  mm occurred over a period of 457 days, yielding a corrosion rate estimate of  $0.37 \pm 0.18$  mm year<sup>-1</sup>.

#### 2.36.4.2.3 Bayesian methods

In many corrosion applications, fitness for purpose is assessed using the remaining wall thickness (RWT). However, the RWT varies with the initial wall thickness, WT, independently of the corrosion process. The primary corrosion damage measure is actually the wall loss, which is independent of the initial wall thickness. For a given wall loss,  $X = x$ , the determination of the RWT depends on the measurement method. Generically, measurement methods determine either the material remaining or the material lost. In the first case, the RWT is measured directly as

$$y^{(1)} = (WT - x) + e^{(1)} \quad [52]$$

(for some error  $e^{(1)}$ ), and in the second case, the wall loss is measured directly as  $x + e^{(2)}$  (for some error  $e^{(2)}$ ), giving the apparent RWT

$$y^{(2)} = \text{NWT} - (x + e^{(2)}) \quad [53]$$

where NWT is the nominal wall thickness. However, noting that  $y^{(2)} = (WT - x) + [(NWT - WT) - e^{(2)}]$ , in general, the RWT is given by  $y = (WT - x) + e$ .

Bayesian methods are ideally suited to the problem of varying wall thickness. Wall loss  $X$  is assumed to be independent of the initial wall thickness, WT, and to have a continuous distribution function  $F(x)$ . Hence, conditional on the initial wall thickness,  $WT = w$ , the wall loss has the truncated distribution function  $F(x)/F(w)$  and differentiation gives the conditional density,

$$f(x|WT = w) = \frac{f(x)}{F(w)} \quad [54]$$

Hence, the first application of Bayes' rule is to obtain the posterior as

$$p(\theta, WT = w|x) = \frac{1}{c(x)} \frac{f(x, \theta)}{F(w, \theta)} p(\theta) p_{WT}(w) \quad [55]$$

where the normalizing constant is given by

$$c(x) = \int \left[ \int \frac{p_{WT}(w)}{F(w, \theta)} dw \right] f(x, \theta) p(\theta) d\theta \quad [56]$$

Now the posterior density  $p(\theta|x)$  can be obtained by integrating over the initial wall thickness to give

$$p(\theta|x) = \frac{f(x, \theta)}{c(x)} p(\theta) \int \frac{p_{WT}(w)}{F(w, \theta)} dw \quad [57]$$

This formula explicitly quantifies the effect of uncertainty in initial wall thickness. In cases wherein the wall loss is small compared with the initial wall thickness,  $F(w, \theta) \cong 1$ , and the posterior reduces to

$$p(\theta|x) = \frac{f(x, \theta) p(\theta)}{\int f(x, \theta) p(\theta) d\theta} \quad [58]$$

Having obtained the posterior, the posterior predictive probability of wall loss exceeding a

threshold,  $u$ , is given by integrating over the posterior, that is,

$$\Pr(X > u|x) = 1 - \int F(u, \theta)p(\theta|x)d\theta \quad [59]$$

These results can be extended to the case when the wall loss is measured directly with measurement-error density,  $\varphi(z)$ , since the likelihood conditional on the wall thickness is now given by

$$f(y|WT = w) = \frac{1}{F(w)} \int_{y-w}^y f(y-z)\varphi(z)dz \quad [60]$$

The case in which the RWT is measured directly gives a similar result,

$$f(y|WT = w) = \frac{1}{F(w)} \int_{y-w}^y f(w-y+z)\varphi(z)dz \quad [61]$$

In cases wherein the wall loss can be localized to a 'defect' and there are a large number per component, the problem reduces to considering the maximum wall loss. In case the number of defects is Poisson with mean  $\lambda$ , the maximum wall loss has distribution function  $\exp\{\lambda[1 - F(x)]\}$ .

In many practical situations, the GEV distribution can be used to approximate the distribution of the maximum wall loss. A question of special interest is whether the distribution has an upper bound, which is given by

$$\delta + \frac{\alpha}{\kappa} = X_{(1/e)} + \frac{X_{(0.5)} - X_{(1/e)}}{1 - (\ln 2)^\kappa} \quad [62]$$

where  $X_{(p)}$  denotes the  $p$  the quantile of the distribution. Evidently, since the quantiles are readily estimated by the sample values, uncertainty in the putative upper bound is dominated by uncertainty in the shape parameter,  $\kappa$ . Indeed, any Bayesian analysis using the GEV is very sensitive to the shape-parameter prior, and more experience is required to assess whether the results are suitably robust for practical application.

**Figure 14** shows an analysis of wall thickness data produced by the S-IDAP package described by Hoeve *et al.*<sup>61</sup> S-IDAP makes Bayesian predictions based on a number of alternative models in addition to the linear or constant corrosion rate model. These include a genuine change in corrosion rate as well as other data anomalies such as an outlier or incorrect measurement. Given prior probabilities for the candidate models, Bayes' rule can be used to calculate the posterior probability of each model, thereby indicating the most probable model. Such information is useful for reviewing the data to ensure a robust prediction. The final prediction is a weighted

combination of the predictions from each model. According to Bayes' rule, the optimal prediction is obtained by weighting the predictions from each model with the model's posterior probability.

### 2.36.4.3 Pit Depth Data

For pitting corrosion, analysis of inspection data is generally focused on predicting the time at which the deepest pit is expected to penetrate through the complete thickness of the inspected item. Of course, extreme value techniques are naturally suited to this problem. Furthermore, pits in engineering metals and alloys generally initiate at defects, such as nonmetallic inclusions or intermetallic particles, such that the number of potential pit initiation sites is typically very large. It is also well known that many pits will initiate and propagate for short periods, producing only small pits, while a relatively small number of pits may become 'stable' and grow to significant depths from an integrity perspective. For example, experimental data presented by Bhakta and Solomon<sup>63</sup> show pit densities for low carbon steel in the range 100–350 cm<sup>-2</sup>. Coupled with the resolution of the measuring instrument, this implies that data sets consisting of all practicably measurable pits at a given site may inherently consist of data incorporating a known and (relative to the majority of the initiated pits) large threshold.

#### 2.36.4.3.1 Extreme value analysis for life prediction

**Figure 16** shows all pit depths over 6  $\mu\text{m}$ , as found by inspection of two copper-plated 316L stainless steel college roofs in the south of England. The first roof had been exposed for 1523 days and the second for 883 days. The mean exceedance plots for these data gave a slope that was not significantly different from zero after applying the usual least-squares criteria, implying a simple exponential distribution for these exceedances, and hence a Type-I EV for maxima.

Time dependence can be incorporated into the fitted GPD models by assuming the square root law for growth (see other comments in this chapter), which then had exponential type probability density functions

$$f(y) = 2.893t^{-0.5} \exp[-2.893(y-6)t^{-0.5}], \quad y > 6 \text{ Roof 1} \quad [63]$$

with mean  $0.346t^{0.5}$ , and

$$f(y) = 1.062t^{-0.5} \exp[-1.062(y-6)t^{-0.5}], \quad y > 6 \text{ Roof 2} \quad [64]$$

with mean  $0.0941t^{0.5}$ .

**Figure 16** All pit depths over 6  $\mu\text{m}$ , as found by inspection of two copper plated 316L stainless steel college roofs in the south of England. The first roof had been exposed to the weather for 1523 days and the second for 883 days.

The count of exceedances over the specified value will follow a Poisson distribution with mean rates over the whole roof

$$\begin{aligned}
 &= 4.3A \exp[-2.893(\gamma - 6)t^{-0.5}] \text{ for Roof 1} \\
 &= 3.9A \exp[-1.062(\gamma - 6)t^{-0.5}] \text{ for Roof 2} \quad [65]
 \end{aligned}$$

where  $A = 5\,000\,000\text{ cm}^2$ . Given that the roof (cover) thickness is 400  $\mu\text{m}$ , this reaches a mean count of 1 after 12 years for Roof 1, and after 3 years for Roof 2. This analysis gives the expected time to the first penetration for each roof covering.

In the majority of cases, life prediction based on the analysis of historical data involves the key assumption that the environmental conditions in the future can reasonably be considered similar to those in the past. However, even if this assumption is reasonable on average, over long time periods, the environmental conditions usually vary quite significantly over time. For example, Figure 17 shows the variation of the chloride concentration in an open recirculating cooling water system over several years. Despite this variation, which will be not limited to the chloride level but will extend to many other factors such as pH and inhibitor concentration,

a Japanese survey of carbon steel heat exchangers in cooling water circuits found that the depth of the deepest pit tends to increase with the square root of time over many years of service.<sup>64</sup> From their survey data, they calculated the variation of EV model parameters over time and used this to produce remaining life estimates for exchanger tube bundles in this type of service. Some further discussion and alternative approaches to this problem are provided elsewhere.<sup>65</sup>

#### 2.36.4.3.2 Life prediction models transformable to linearity

A model with profound implications for the extrapolation of long-term corrosion rates in time is the power-law model  $y = at^b$ , as reported in Laycock *et al.*,<sup>32</sup> Aziz and Godard,<sup>66</sup> and de la Fuente,<sup>67</sup> and elsewhere, all with  $b < 1$  and  $b = 0.5$  or  $0.67$  typical. It is important to note that the corrosion rate, that is,  $dy/dt$ , is now time dependent and cannot be reported in isolation as a single number. By assuming a multiplicative error, taking logs of this model produces a straight line regression model, which can be fitted by ordinary least-squares with dependent variable  $y' = \log(y)$ , intercept  $a' = \log(a)$ , slope  $b$ , and

**Figure 17** Distribution of measured chloride concentrations (ppm) in an open recirculating cooling water system, obtained from 1550 measurements over 12 years of operation.

**Figure 18** A true power-law growth curve, with decreasing corrosion rate, fitted through the pit depth data of Pierpoline *et al.*,<sup>48</sup> using the method described in Scarf *et al.*<sup>49</sup> This is compared with fitted straight lines based on (a) first data point plus origin; then (b) first and second data points, both extrapolated to show how prediction errors decrease.

covariate  $x = \log(t)$ , except that  $b$  is of course no longer the corrosion rate. Now, suppose that corrosion is progressing according to such a law, as illustrated in Figure 18, but we only have some current data, collected at time  $t = t_1$ , say. Then, fitting a simple straight line through the origin with these

data will produce the straight line superimposed on the curve as shown in Figure 18, and an extrapolated corrosion rate much in excess of future corrosion rates. Now, suppose that we collect some more data, at a later time  $t_2$  and fit a straight line regression through the two time points we now have, as again

illustrated in [Figure 18](#). This time the predicted corrosion rates are much closer to reality for reasonable extrapolations into the future. This suggests that, where it is convenient to have just a single reportable ‘corrosion rate,’ straight-line regression should be used, with an intercept, utilizing just the latest two or three time points. If more points are available, then the tests for deviations from linearity (as described earlier) can be used to assist in model determination.

#### 2.36.4.4 Intelligent Piggings Data

Pipeline inspections by Intelligent Pigs can produce vast amounts of data, which are typically summarized in lists of ‘features’ with depths greater than some predefined reporting threshold. When comparing the data from two different inspections of the same pipeline, it is often attempted to match the ‘corrosion features’ from the two runs and thereby determine a corrosion rate for each feature. However, for various reasons, such as changes in technology over time, it is often difficult to match all the reported features in this way. Here, we describe methods for analysis of both ‘tracked’ and ‘untracked’ features.

##### 2.36.4.4.1 Untracked features: Pareto distribution example

Suppose that the results of two piggings runs down a large and actively corroding pipeline are presented as two sets of untracked feature depths  $y_{11}, y_{12}, \dots, y_{1n_1}$  at time  $t_1$  and  $y_{21}, y_{22}, \dots, y_{2n_2}$  at time  $t_2$  with  $n_2 \geq n_1$ . Because the later survey may have new features, the two data mean  $\bar{y}_1$  and  $\bar{y}_2$  may not provide a sound

estimate of the corrosion rate. Indeed, if there are enough fresh features, the second mean could be smaller than the first. Instead, consider the  $n < \min(n_2, n_1)$  largest order statistics  $y_{(11)}^* > y_{(12)}^* > \dots > y_{(1n)}^*$  and  $y_{(21)}^* > y_{(22)}^* > \dots > y_{(2n)}^*$  for the two series. Since interest will center on the growth rate of the largest values, it seems sensible to use a mean exceedance plot to decide on a common cutoff point for the two ordered series based on the same count of measurements to maintain rough comparability and equivalence to a fully tracked sequence. A plot of the two fitted GPD distributions for a simulated set of piggings data that has been filtered and processed in this manner can be seen in [Figure 19](#). The modal shift between these two roughly parallel curves is 2.85 mm and the runs were 6 months apart, implying a corrosion rate of  $5.7 \text{ mm year}^{-1}$ .

##### 2.36.4.4.2 Tracked feature comparison

[Figure 20](#) shows a set of 22 tracked feature depths from two piggings runs of a subsea gas pipeline. The tracked features are all from one pipe spool known to have suffered some internal damage early in service life, many years before these two piggings runs. However, there was also a risk of ongoing internal corrosion due to upsets in dewpoint control. The piggings data are expressed as percentage wall thickness lost, with the difference between the two sets of data converted to an implied wall loss in millimeters – based on a nominal original wall thickness of 15.9 mm. Since 7 of the 22 values are negative, with a maximum absolute value of 1.27 mm, there is substantial measurement error involved. The average

**Figure 19** Fitted Pareto distributions for the largest 1500 order statistics from two successive piggings runs (simulated data only). The modal shift between these two roughly parallel curves is 2.85 mm, and the runs were 6 months apart, implying a corrosion rate of  $5.7 \text{ mm year}^{-1}$ .

**Figure 20** A set of 22 tracked feature depths from two pigging runs of a subsea gas pipeline. These features are all from one pipe spool known to have suffered some internal damage early in service life, many years before these two pigging runs.

implied wall loss is  $-0.426$  mm with a standard error of  $0.208$  mm (so an implied corrosion rate of  $-0.065$  mm year $^{-1}$  with standard error of  $0.032$  mm year $^{-1}$ ). Note that this average loss is based on all the 22 values. Discarding the seven negative values as ‘erroneous’ would produce a severely biased estimate of the true corrosion rate – since, without further information, it must be assumed that the unknown measurement errors are as likely to be positive as negative. An inferred tolerance for these measurements of  $\pm 1.3$  mm implies a measurement error standard deviation of  $0.65$  mm with variance of  $0.4225$ . The variance of the recorded wall loss data is  $0.9520$ ; hence if we assume an additive corrosion process, the implied Wiener noise variance (see Section 2.36.1) is  $(0.9520 - 2 \times 0.4225) = 0.1070$  over the 2393 days between the pigging runs, or  $0.0163$  scaled to 1 year – so a standard deviation of  $0.13$  mm year $^{-1}$ . Since the 95% (one-sided) point from Student’s  $t$ -distribution on  $(22 - 1) = 21$  degrees of freedom is  $1.72$ , and a 95% upper prediction bound on future values for the corrosion rate will be  $-0.065 - 1.72 \times \sqrt{(0.032^2 + 0.0163)} = -0.29$  mm year $^{-1}$ , which coincides with the single (so  $\sim 5\%$ ) maximum observed corrosion rate found in the 22 measured annual corrosion rates.

#### 2.36.4.5 Optimizing Inspection and Repair Intervals

Corrosion damage and cracks detected by nondestructive inspection may be subject to repair. Such

maintenance will, in general, need to be carried out within an effective maintenance program.<sup>68–70</sup> Based on assumptions about the rate of corrosion or crack growth, the consequences of failure, the cost of inspection and repair, and data to estimate parameters relating to these quantities, maintenance decision-making can follow. In particular, the optimum time between inspections may be determined.

##### 2.36.4.5.1 Planning inspections for cracks

In the simplest case, assume that an inspection is carried out at  $T$  time units since the last inspection or failure; inspections are perfect (all crack defects are detected at inspection and repaired) so that they renew the system; on failure, all crack defects are repaired, and the system is renewed; the cost inspection including the repair of crack defects is fixed at  $C_p$ ; and the cost of failure is  $C_f$ . Denote the time to failure by  $X$ , then

$$\begin{aligned} F_X(t) &= \Pr(X \leq t) = \Pr(Z_{\max,t} > z_f) \\ &= 1 - F_{\max,t}(z_f) \end{aligned} \quad [66]$$

where  $F_{\max,t}(z_f)$  is the distribution of the maximum crack depth at time  $T$ . The long-run cost per unit time is given by the renewal-reward theorem<sup>71</sup>:

$$C(T) = E(U)/E(V) \quad [67]$$

where  $E(U)$  is the expected cost of an renewal interval, and  $E(V) = E\{\min(X, T)\}$  is the expected

length of a renewal interval. The renewal interval is defined as the time between successive renewals. Now

$$E(U) = C_f - (C_f - C_p)F_{\max,T}(z_f) \quad [68]$$

since the cost of a renewal interval is  $C_p$  if the renewal interval ends with an inspection that occurs with probability  $F_{\max,T}(z_f)$ , and  $C_f$  if the renewal interval ends with a failure that occurs with probability  $1 - F_{\max,T}(z_f)$ . Also,

$$\begin{aligned} E(V) &= E\{\min(X, T)\} = \int_0^T \{1 - F_X(t)\} dt \\ &= \int_0^T F_{\max,t}(z_f) dt \end{aligned} \quad [69]$$

Thus,

$$C(T) = \{C_f - (C_f - C_p)F_{\max,T}(z_f)\} / \int_0^T F_{\max,t}(z_f) dt \quad [70]$$

This is the classic age-based replacement policy of Barlow and Proschan [72].  $C(T)$  is minimized with respect to  $T$  to obtain  $T^*$ , the cost-optimal age limit for inspection (or more generally, preventive maintenance). For this purpose,  $F_{\max,t}(z_f)$ ,  $C_p$ , and  $C_f$  must be specified and  $C(T)$  minimized. Differentiating eqn [70] with respect to  $T$  and setting the derivative equal to zero, we obtain

$$\begin{aligned} \{f_{\max,T^*}(z_f)/F_{\max,T^*}(z_f)\} \int_0^{T^*} F_{\max,t}(z_f) dt \\ + F_{\max,T^*}(z_f) = C_f/(C_f - C_p) \end{aligned} \quad [71]$$

where  $f_{\max,t}(z_f)$  is the density function of the maximum crack depth.  $T^*$  can be found by solving eqn [71] numerically, or by plotting  $C(T)$  against  $T$  for various values of  $T$ .

If the cost of crack repairs is additional to the cost of inspection, the cracks costing  $C_r$  each to repair, then the optimum inspection interval does not depend on  $C_r$ , because the expected cost of a renewal interval  $E(U)$  increases by  $\lambda C_r \times E(V)$ , where  $\lambda$  is the rate of crack initiation – a longer inspection interval will result in more cracks developing. Thus, the long-run cost per unit time,  $C(T)$ , increases by a factor  $\lambda C_r$  that does not depend on  $T$ .

#### 2.36.4.5.2 Optimizing inspections with unknown cost of failure

Often in practice, it is difficult to specify the cost of failure. Engineers may be happier to prescribe a required reliability. Such a required reliability is best expressed in terms of the operational reliability, which is defined as the distribution of the time

between operational failures of the system. Assuming that system renewal intervals are independent of one another, the time of any failure can be taken as time origin, and events up to the first subsequent failure can be considered without loss of generality. Thus, if the time to the first operational failure of the system is denoted by  $Y_1$  and subsequent time to second operational failure by  $Y_2, \dots$ , then  $Y_1, Y_2, \dots$  are independent and identically distributed with distribution function  $F_Y(y)$ , say. It follows that

$$\begin{aligned} R_Y(y) &= R_X(y - nT)\{R_X(T)\}^n, \\ (nT \leq y < (n+1)T, n = 0, 1, \dots) \end{aligned} \quad [75]$$

where  $R_Y(y) = 1 - F_Y(y)$  is the operational reliability function. This result is given in this form by Lewis.<sup>73</sup> The mean and variance of this distribution can be determined explicitly:

$$\begin{aligned} E(Y) &= \mu_T + T\{1 - F_X(T)\}/F_X(T) \\ &= \int_0^T (1 - F_X(x))dx/F_X(T) \\ \text{var}(Y) &= \sigma_T^2 + T^2\{1 - F_X(T)\}/\{F_X(T)\}^2 \end{aligned} \quad [76]$$

where  $\mu_T = E(X|X < T)$  and  $\sigma_T^2 = \text{var}(X|X < T)$ . We call  $E(Y)$  the mean time between operational failures (MTBOF). For small  $T$ ,  $\mu_T \sim 0$  and  $\sigma_T^2 \sim 0$ . Therefore,  $E(Y) \sim T/F_X(T)$ ,  $\text{var}(Y) \sim \{T/F_X(T)\}^2$ , and  $Y$  has approximately an exponential distribution with mean  $T/F_X(T)$ . This approximation is supported by the results of Xie *et al.* [74]. Furthermore,

$$F_X(T)/T = \Pr(Z_{\max,T} > z_f)/T \quad [77]$$

can be interpreted as the operational failure rate.

Thus, given a reliability constraint that is expressed in terms of the MTBOF, the required inspection interval  $T^*$  can be obtained from eqn [77] and using the fact that  $F_X(t) = 1 - F_{\max,t}(z_f)$ . Note that an implied cost of failure,  $C_f$ , can be determined by substitution of  $T^*$  in eqn [71].  $T^*$  can also be determined by specifying the operational failure rate in eqn [77].

#### 2.36.4.5.3 Crack inspection case study

Maximum crack depths were measured on identical circular welds at locations in two identical plants after varying amounts of operating time (Figure 21). A number of welds were subjected to repeated inspection by NDT, but here, only the first inspections are considered. The complete dataset is presented in Scarf *et al.*<sup>75</sup> Where a weld was inspected and no crack found, this was recorded as a zero. At inspection, welds were repaired. It was of interest

**Figure 21** Maximum crack depth against age-at-first-inspection for 59 circular welds from two identical plants – jitter added to depths to distinguish all datapoints.

**Table 3** Parameter estimates for the model: Poisson process of crack initiation (rate  $\lambda$ ) with distribution of crack depth given by eqn [47]

Parameter	Estimate
$\alpha_0$	7.092
$\beta$	1.645
$\gamma$	0.00079
$\lambda$	0.00013

to the engineers operating the plant to determine if there was some positive trend in crack depth with age (or time since last inspection), and if so, at what rate cracks were ‘growing’; and also to determine how often they should carry out costly inspections.

The crack depth data are used here to demonstrate the estimation of the maximum crack depth distribution (eqn [49]). The estimated parameters are shown in Table 3. These imply that visible cracks initiate at a rate per weld of one every 7937 operating hours and then subsequently grow at a mean rate given by  $\mu = \alpha_0 \Gamma(1 + 1/\beta) \tau^\gamma = 6.32 \tau^{0.000785}$ . This growth rate implies that, for example, the mean depth of a crack that has been growing for 10 000 h is 6.37 mm. The estimated growth rate is extremely slow, suggesting that the cracks were in fact not growing at all and were present in the welds from new.

To demonstrate the methods of this section further, the growth rate parameter is taken to be  $\gamma = 0.3$ , and  $\alpha_0$  is rescaled. Taking  $\alpha_0 = 0.4$  implies that the mean depth of a crack that has been growing for 10 000 h is 6.34 mm, and 9.23 mm for one growing for 35 000 h. The distribution of the maximum crack depth over the entire system (assuming 60 welds on the system) at time  $T$  is then as shown in Figure 22.

**Figure 22** The distribution (probability density) of the maximum crack depth over the system at various times,  $T$ , in operating hours.

The probability density is drawn here for various values of  $T$ . The mean maximum depth and the standard deviation of the maximum crack depth are increasing as expected.

The probability of observing a maximum crack depth that is at least as big as some specified threshold can be determined. For example, from Figure 22, there is a significant risk that a maximum crack depth in a weld is larger than 40 mm after 50 000 h ( $P=0.033$ ). This probability rises to 0.727 after 100 000 h of operation.

To consider an optimum time between inspections, assuming perfect inspection and repair (weld renewal), the cost of inspection and repair of welds,  $C_p$ , can be considered as the unit of cost. Then, the cost of failure,  $C_f$ , need only be specified in terms of the cost of inspection and repair. The failure-critical threshold for the maximum crack depth must also be specified. This is taken to be 40 mm. Then, the long-run cost per unit time can be determined for various  $T$ . This is shown in Figure 23(a) with  $C_f = 4C_p$ . The optimum inspection interval is  $\sim 55$  000 h. The sensitivity to  $C_f$  and  $z_f$  may be investigated simply by determining  $T^*$  for various values of  $C_f$  and  $z_f$ . For example, for a scenario in which the cost of failure is considerably higher than the cost of inspection, say  $C_f = 10C_p$ ,  $T^*$  reduces to  $\sim 45$  000 h. Where an operational reliability is required, this is done most simply by specifying an operational failure rate, eqn [77], and solving for  $T^*$  by trial and error. In Figure 23(b), the operational failure rate is plotted against  $T$ . Given a required operational reliability,  $T^*$  may be read off this graph. Note that this  $T^*$  then implies a cost of

**Figure 23** (a) The long-run cost per unit time,  $C(T)$ , against  $T$ , with  $C_f = 4C_p$  and  $z_f = 40\text{mm}$ . (b) Time between inspections against operational failure rate,  $\Pr(Z_{\max,T} > z_f)/T$  with  $z_f = 40\text{mm}$ .

failure that may be calculated and used to confirm engineering judgment about these quantities. An operational reliability of (at most) one failure for every  $5 \times 10^6$  operating hours requires that the inspections take place every 40 000 h, which in turn implies that  $C_f = 20C_p$  (approximately).

The calculations mentioned earlier may be performed on a spreadsheet. The integral in eqn [49] may be evaluated most simply using Simpson's rule. For the calculation of the long-run cost (eqn [70]), the integral in the denominator can be calculated likewise and noting that  $F_{\max,t}(z_f) \approx 1$  for small  $t$  (here for  $t \leq 20\,000$ ). These approximations provide sufficient accuracy for optimization purposes, given that the cost function is relatively flat in the region of the optimum.

### 2.36.5 Corrosion Monitoring

The science of electrochemical noise monitoring began in the 1980s<sup>76,77</sup> and has since extended into commercially available corrosion monitoring techniques. The standard noise analysis techniques are typically built on incrementally additive assumptions for corrosion, as in the theoretical 'shot noise' models for pitting and crevice corrosion proposed by Eden, Cottis, and other workers.<sup>37,38</sup> These result in Poisson

models and consequently have variance equal to the mean, which can be approximated by Normal distributions. More generally, statistical analysis methods may ignore the ordering of the measured potential or current values by using sequence-independent parameters such as the mean, standard deviation, skew, and kurtosis, or they may take the sequencing into account by computing the autocorrelation function, power spectral density PSD –  $\psi_E$  for potential, or  $\psi_I$  for current – or higher-order spectra. When potential and current noise are measured simultaneously, electrochemical noise resistance  $R_n$ , electrochemical noise impedance, characteristic charge  $q$ , and characteristic frequency  $f_n$  can be calculated. The  $R_n$  is obtained as the ratio of the standard deviation of potential to the standard deviation of current, justified by appealing to the definition of electrical power for an alternating current. The PSD referred to is that at low frequencies, where the noise is white (hence, the PSD is frequency-independent). Electrochemical noise impedance can be estimated in essentially the same way as the  $R_n$ , by dividing the PSD of the potential noise by the PSD of the current noise. Several researchers have analyzed the relationship between  $R_n$  and the polarization resistance  $R_p$ , and some claim to have proved that the two are equivalent.<sup>78</sup>

#### 2.36.5.1 Threshold Techniques

When this technique is used on a correlated time-series, such as the current noise plot in Figure 24(a), preliminary filtering of the data is required so as to produce a set of statistically independent measured maxima. The most widely adopted method is declustering (see Coles<sup>33</sup>, p. 99). In this, an empirical rule is used to define isolated clusters of exceedances, followed by extraction of the maximum within each such cluster. In meteorology, this is sometimes described as 'rainstorm identification'. The empirical spreadsheet formula with a bandwidth of 10 units used to extract the maxima in Figure 24(b) from the noise data in Figure 24(a) was

```
IF(AND(((MAX(F11:F20)–AVERAGE(F11:F20))<1),
((MAX(F10:F20)–AVERAGE(F10:F20))>1)),1,0)
*F20IF(AND((MAX(F11:F20)–AVERAGE
(F11:F20))<1),
((MAX(F10:F20)–AVERAGE(F10:F20))>1)),1,0)
*F20
```

**Figure 24** Threshold analysis techniques applied to electrochemical noise measurements. (a) Raw current noise data, (b) extracted peaks, and (c) mean exceedance plot for the current noise measurements, with fitted straight line at selected threshold.

This is for data row 20 updated as usual for other rows. The mean exceedance plot for these data can be seen in **Figure 24(c)**, in which a threshold of 200  $\mu\text{A}$  was used as a cutoff point for fitting the straight line. The statistical package Xtremes, which is supplied with the book by Reiss and Thomas,<sup>56</sup> offers an automated procedure for selecting this threshold.

### 2.36.6 Summary and Conclusions

Statistical techniques have long been used in both corrosion science and engineering. Rigorous data analysis can help to ensure that the maximum possible benefit is achieved from analysis of corrosion data, be it from laboratory experiments, or plant inspection programs. However, the full range of available methods is not widely used in either field. For corrosion engineering in particular, modern computer technology and readily available statistical software packages present a considerable opportunity for wider use of advanced analysis methods that will make better use of limited inspection data and provide quantitative measures of uncertainty, thereby enabling improved decision making. Key applications include estimating the maximum extent of damage from sample inspections and estimating corrosion rates from wall thickness measurements at different times. While values extrapolated far beyond the sampling region have to be interpreted with care, extreme value analysis provides an established method for carrying out such predictions. Also, when combined with risk-based inspection and reliability engineering methodologies, statistical techniques can be used to guide decisions on the required extent of inspection, especially in relation to piping systems wherein only relatively small sample inspections are practically feasible.

### 2.37.1 Introduction

For the purposes of this chapter, modeling is defined as the construction of a mathematical-based description of the corrosion process that permits the calculation of expected corrosion behavior for arbitrary conditions within a specified range. While physical models (i.e., practical systems that are expected to have the same behavior as a real corrosion system) have been used (e.g., to study current distribution in cathodic protection), these have received relatively little attention recently. In contrast, the rapidly increasing power of computer hardware and software has led to a huge growth in the use of mathematical models, usually using numerical methods to solve the complex systems of equations that govern most corrosion processes.

### 2.37.2 Applications of Modeling

There are two distinct reasons for the development of models of corrosion processes:

1. *Prediction of behavior:* Many would expect that the construction of predictive models (i.e., models that can predict corrosion behavior over a range of conditions) would be the most important aspect of corrosion modeling, and this is certainly a common view. For some well-defined problems,

such as the distribution of cathodic protection current in a uniform conductive environment such as seawater, predictive models based on ‘first-principles’ methods can be very accurate and form an important tool in the corrosion engineer’s armoury. However, many corrosion processes are very complex and the construction of first-principles predictive models is currently difficult (but see **Chapter 2.38, Modeling of Aqueous Corrosion** and **Chapter 2.39, Predictive Modeling of Corrosion**), and practical predictive models often use relatively simple functions (possibly, but not necessarily, based on theoretically expected dependencies) that are calibrated using measured data. Thus, such models are often concerned more with fitting functions to data than with real understanding of the corrosion process. One such method, the use of neural networks, is discussed in **Chapter 2.40, Neural Network Methods for Corrosion Data Reduction**, while other data-based models may be discussed in the context of the specific corrosion process.

2. *Testing and developing understanding:* While it may not be appreciated by those who have not attempted to develop models, one of the most powerful applications of modeling is to test understanding of mechanisms. One of the fundamental reasons for this is that the construction of a theoretically-based model requires every aspect of a mechanism to be exactly defined and quantified, which is often not done (and may be essentially impossible without constructing a model, due to the complexity of corrosion processes) in the absence of the rigorous analysis required by the modeling process. Then the comparison of the output of the model with

observations provides a challenging test of the precision of understating of the mechanism. Furthermore, the process of creating a model almost inevitably enhances the understanding of the process by those involved in the creation – a challenge for modelers is often to convey their enhanced understanding to others.

### 2.37.3 Modeling Methods

This section covers a number of modeling methods:

1. Modeling of electrochemical reactions  
Electrochemical kinetic theory is well-developed, and accurate models of the behavior of pure metals in reasonably simple environments can be developed. This is covered in **Chapter 2.38, Modeling of Aqueous Corrosion** and **Chapter 2.39, Predictive Modeling of Corrosion**, which demonstrates the detail required for the construction of accurate first-principles models.
2. Modeling of spatial distribution  
For a number of corrosion processes, such as galvanic corrosion, pitting corrosion, crevice corrosion, and cathodic protection, the challenge is to evaluate the distribution of reaction over the surface of a component. In the simplest cases, such as cathodic protection, it is sufficiently accurate to treat the problem as that of potential and current distribution in a uniform resistive medium. In more challenging cases, such as pitting and crevice corrosion, it is necessary to account for changes in the chemistry of the solution and the consequent changes in reaction kinetics. In this case, the techniques in the previous section become important, although most work in this area tends to use rather simplified models of interfacial chemistry. Such models have been developed for many years, but the advent of general-purpose finite element programs has made these methods much more accessible. **Chapter 2.39, Predictive Modeling of Corrosion** provides examples of the state-of-the art in such modeling, but does not go into the details of the principles underlying the spatial aspects of the models, which are described in outline in the following section.
3. Data-based modeling  
Owing to the complexity of the interactions between metallurgical structure, environment and mechanical stress, many corrosion processes are not yet amenable to theoretically-based modeling, and predictive models must therefore be based on measured data. Such models are then highly

dependent on both the quality and the quantity of the measured data on which they are based. We can define the ‘problem domain’ for a particular set of measured data as being a region in a multidimensional space where each dimension represents one of the variables that have a significant effect on the behavior. For accurate models, it is important that the measured data provide an adequate coverage of the problem domain and that the measured data have well-defined values for all of the dimensions of the multidimensional space. Unfortunately, this is rarely achieved, especially where real service data are concerned. The modeling of the data then becomes a problem of fitting the ‘best’ function to the measured values. For small data sets, it is usually necessary to make some simplifying assumptions about the behavior, such as assuming linear dependencies and neglecting interactions between variables. If sufficient information is available, more complex functions can be fitted, such as higher-order polynomials. Neural network methods (introduced in **Chapter 2.40, Neural Network Methods for Corrosion Data Reduction**) provide a particularly interesting approach, whereby the functional relationship is effectively determined by the fitting process, rather than being defined in advance.

### 2.37.4 Approaches to Modeling Spatial and Time Distribution

When we are concerned with the spatial distribution of corrosion (e.g., when attempting to model crevice corrosion or pitting corrosion), either for the final steady state or for incorporating the evolution over time, the problem can almost invariably be expressed as requiring the solution of a set of partial differential equations over the space and time concerned (the ‘problem domain’) with specified boundary conditions. Occasionally, it is possible to obtain an analytical solution, but usually only in highly simplified cases. Consequently, it is normally necessary to use a numerical method to obtain a solution. As a generalization, many of the numerical methods aim at converting the differential equations into a finite (but usually large) set of simultaneous difference equations. These can then be solved by conventional methods for the solution of simultaneous equations (essentially these write the simultaneous equations as a matrix equation that can be solved by matrix inversion). There are three approaches to this.

### 2.37.4.1 Finite Difference Methods

In the finite difference method, the problem domain is covered by a regular grid of points, the objective then being to determine the values corresponding to the solution to the system of differential equations at the grid points. These will be points with a constant spacing along a line for a 1-dimensional problem, crossing points of a square grid for a 2-dimensional problem and points on a cubic grid for a 3-dimensional problem. (Some finite difference methods use grid spacings that vary according to a regular pattern, and these may offer advantages for electrochemical problems.<sup>1</sup>) Then the solution can be approximated by replacing the differential equations by the corresponding difference equations. For the detailed mathematics of the process (and an indication of the large variety of methods that have been developed to obtain a solution), the readers are referred to Britz,<sup>1</sup> but we can illustrate the method by a simplified explanation.

We shall consider one of the simplest classes of problems, that of determining the steady-state potential distribution in a uniform 2-dimensional conductor (e.g., a conductive sheet). If we consider a grid point somewhere in a 2-dimensional array (Figure 1), it is easy to see that the best estimate of the true value of the potential at a point is the average of the corresponding potentials in the four nearest neighbors. Thus, if  $V[x,y]$  is the potential at point  $x, y$ , we can write

$$V[x,y] = (V[x-1,y] + V[x+1,y] + V[x,y-1] + V[x,y+1])/4$$

Edge and corner points and internal boundaries will obviously have to be handled specially (and this is where the boundary conditions will be introduced). Writing the appropriate equations for all grid points leads to a set of simultaneous equations, which can be solved by matrix inversion or by a range of alternative

techniques (iterative solution methods are usually used, because the arrangement of grid points in the problem domain is normally very regular; these effectively implement the matrix inversion in a very efficient manner by taking advantage of the regularity). The method has the advantage of conceptual simplicity and relatively easy implementation without specialist software. However, it does not handle complex geometries very well and it is inefficient for problems where small regions need to be analyzed in detail in a large problem domain (since this requires a very large number of very closely spaced points).

### 2.37.4.2 Finite Element Method

The limitations of the finite difference method are, to an extent, a result of the requirement to use an array of elements of constant size and shape. The finite element method provides the ability to use elements of arbitrary (and variable) size and shape, although at the expense of more complex mathematics; we shall not attempt to explain the mathematical basis here (see the Comsol web site<sup>2</sup> for extensive documentation on the method and its application to electrochemical problems). Fortunately several programs, both commercial and open-source, are available to handle finite element problems. Most of these are targeted to well-defined problems such as stress analysis and the analysis of heat flow in uniform media. Heat flow is slightly more complex than current flow, due to the heat capacity of the material, but the steady-state temperature distribution will be identical to the steady-state voltage distribution. Because of the greater generality and greater practical significance, program literature will usually refer to the analysis of thermal rather than electrical problems.

Some programs<sup>3</sup> are able to handle problems involving multiple physical processes (such as diffusion, migration, and reaction) and provide a simple

**Figure 1** 2-Dimensional grid for finite difference analysis of potential distribution.

way to analyze problems associated with the distribution of corrosion processes.

#### **2.37.4.3 Boundary Element Method**

Both the finite difference and finite element methods need to fill the problem domain with elements, and consequently, it is often necessary to use very large numbers of elements, with the result that very large matrices need to be inverted (the matrix size required is approximately proportional to the square of the number of elements). The boundary element method is based on analyzing only elements on the boundaries of the problem domain. This leads to a major reduction in the number of elements required, and hence the size of matrix that needs to be inverted. However, the computational benefits are not quite as significant as this would suggest, as the matrix that needs to be inverted is usually much more completely filled than for the other methods, and the inversion is consequently much slower for given matrix dimensions. Furthermore, the boundary element method can only be used for a subset of possible characteristics within the

problem domain; fortunately the electrical behavior of a uniform conductive material can be handled. Hence this method is popular for the solution to current distribution problems in cathodic protection. A subsidiary benefit of the method is that it can handle problem domains with no exterior boundary (i.e., the conductive medium can extend to infinity), which is particularly useful for cathodic protection problems. It is beyond the scope of this article to describe the mathematical basis of the boundary element method and the readers are referred to appropriate texts.<sup>4</sup> As with the finite element method, commercial software is available to implement the boundary element method.

 $i_c$  Cathodic current density  
 $i_{c,\text{ct}}$  Charge-transfer contribution to the cathodic current density  
 $i_{c,L}$  Limiting cathodic current density  
 $i_{\text{corr}}$  Corrosion current density  
 $i_p$  Passive current density  
 $i_{\text{rp}}$  Current density limit for measuring repassivation potential  
 $i_0$  Exchange current density  
 $i^*$  Concentration-independent coefficient in expressions for exchange current density  
 $J_i$  Flux of species  $i$   
 $k_{\text{ads}}$  Adsorption rate constant  
 $k_{\text{des}}$  Desorption rate constant  
 $k_i$  Reaction rate constant for reaction  $i$   
 $k_{m,i}$  Mass transfer coefficient for species  $i$   
 $K$  Equilibrium constant  
 $K_{\text{ads}}$  Adsorption equilibrium constant  
 $K_{\text{sp}}$  Solubility product  
 $l_i$  Reaction rate for  $i$ th reaction  
 $m_i$  Molality of species  $i$   
 $m_0$  Standard molality of species  $i$   
 $n_i$  Number of moles of species or electrons  
 $Nu$  Nusselt number  
 $Pr$  Prandtl number  
 $R$  Gas constant  
 $R_k$  Rate of production or depletion of species  $k$   
 $Re$  Reynolds number  
 $S$  Supersaturation  
 $Sc$  Schmidt number

$Sh$  Sherwood number  
 $t$  Time  
 $T$  Temperature  
 $u_i$  Mobility of species  $i$   
 $v_i$  Rate of reaction  $i$   
 $V$  Linear velocity  
 $z$  Direction perpendicular to the surface  
 $z_i$  Charge of species  $i$   
 $\alpha$  Thermal diffusivity  
 $\alpha_i$  Electrochemical transfer coefficient for species  $i$   
 $\beta$  Tafel coefficient using natural logarithms  
 $\gamma_i$  Activity coefficient of species  $i$   
 $\delta_i$  Nernst layer thickness for species  $i$   
 $\Delta G_{\text{ads},i}$  Gibbs energy of adsorption for species  $i$   
 $\Delta H^\ddagger$  Enthalpy of activation  
 $\Delta\Phi$  Potential drop  
 $\epsilon$  Dielectric permittivity  
 $\eta$  Dynamic viscosity  
 $\theta_i$  Coverage fraction of species  $i$   
 $\theta_p$  Coverage fraction of passive layer  
 $\lambda$  Thermal conductivity  
 $\mu_i$  Chemical potential of species  $i$   
 $\mu_i^0$  Standard chemical potential  
 $\bar{\mu}_i$  Electrochemical potential of species  $i$   
 $\nu$  Kinematic viscosity  
 $\nu_i$  Stoichiometric coefficient of species  $i$   
 $\rho$  Density  
 $\Phi$  Electrical potential  
 $\xi_i$  Electrochemical transfer coefficient for reaction  $i$   
 $\omega$  Rotation rate  
 $\nabla$  Vector differential operator  
 $\equiv X$  Surface species  $X$

### 2.38.1 Introduction

Aqueous corrosion is an extremely complex physical phenomenon that depends on a multitude of factors including the metallurgy of the corroding metal, the chemistry of the corrosion-inducing aqueous phase, the presence of other – solid, gaseous, or nonaqueous liquid – phases, environmental constraints such as temperature and pressure, fluid flow characteristics, methods of fabrication, geometrical factors, and construction features. This inherent complexity makes the development of realistic physical models very challenging and, at the same time, provides a strong incentive for the development of practical models to understand the corrosion phenomena, and to assist in their mitigation. The need for tools for simulating aqueous corrosion has been recognized in various industries including oil and gas production and

transmission, oil refining, nuclear and fossil power generation, chemical processing, infrastructure maintenance, hazardous waste management, and so on. The past three decades have witnessed the development of increasingly sophisticated modeling tools, which has been made possible by the synergistic combination of improved understanding of corrosion mechanisms and rapid evolution of computational tools.

Corrosion modeling is an interdisciplinary undertaking that requires input from electrolyte thermodynamics, surface electrochemistry, fluid flow and mass transport modeling, and metallurgy. In this chapter, we put particular emphasis on corrosion chemistry by focusing on modeling both the bulk environment and the reactions at the corroding interface. The models that are reviewed in this chapter are intended to answer the following questions:

1. What are the aqueous and solid species that give rise to corrosion in a particular system? What are their thermophysical properties, and what phase behavior can be expected in the system? These questions can be answered by thermodynamic models.
2. What are the reactions that are responsible for corrosion at the interface? How are they influenced by the bulk solution chemistry and by flow conditions? How can passivity and formation of solid corrosion products be related to environmental conditions? How can the interfacial phenomena be related to observable corrosion rates? These questions belong to the realm of electrochemical kinetics and mass transport models.
3. What conditions need to be satisfied for the initiation and long-term occurrence of localized corrosion? This question can be answered by electrochemical models of localized corrosion.

These models can be further used as a foundation for larger-scale models for the spatial and temporal evolution of systems and engineering structures subject to localized and general corrosion. Also, they can be combined with probabilistic and expert system-type models of corrosion. Models of such kinds are, however, outside the scope of this review, and will be discussed in companion chapters.

### 2.38.2 Thermodynamic Modeling of Aqueous Corrosion

Historically, the first comprehensive approach to modeling aqueous corrosion was introduced by Pourbaix in the 1950s and 1960s on the basis of purely thermodynamic considerations.<sup>1</sup> Pourbaix<sup>1</sup> developed the  $E$ -pH stability diagrams, which indicate

which phases are stable on a two-dimensional plane as a function of the potential and pH. The potential and pH were originally selected because they play a key role as independent variables in electrochemical corrosion. Just as importantly, they made it possible to construct the stability diagrams in a semianalytical way, which was crucial before the advent of computer calculations. Over the past four decades, great progress has been achieved in the thermodynamics of electrolyte systems, in particular for concentrated, mixed-solvent, and high temperature systems. These advances made it possible to improve the accuracy of the stability diagrams and, at the same time, increased the flexibility of thermodynamic analysis so that it can go well beyond the  $E$ -pH plane.

The basic objective of the thermodynamics of corrosion is to predict the conditions at which a given metal may react with a given environment, leading to the formation of dissolved ions or solid reaction products. Thermodynamics can predict the properties of the system in equilibrium or, if equilibrium is not achieved, it can predict the direction in which the system will move towards an equilibrium state. Thermodynamics does not provide any information on how rapidly the system will approach equilibrium, and, therefore, it cannot give the rate of corrosion.

The general condition of thermodynamic equilibrium is the equality of the electrochemical potential,  $\bar{\mu}_i$  in coexisting phases,<sup>2</sup> that is,

$$\bar{\mu}_i = \mu_i + z_i F \phi = \mu_i^0 + RT \ln a_i + z_i F \phi \quad [1]$$

where  $\mu_i$  is the chemical potential of species  $i$ ;  $\mu_i^0$ , its standard chemical potential;  $a_i$ , the activity of the species;  $z_i$ , its charge;  $F$ , the Faraday constant; and  $\phi$  is the electrical potential. The standard chemical potential is a function of the temperature and, secondarily, pressure. The activity depends on the temperature and solution composition and, to a lesser extent, on pressure. The activity is typically defined in terms of solution molality  $m_i$ ,

$$a_i = (m_i/m^0) \gamma_i \quad [2]$$

where  $m^0$  is the standard molality unit ( $1 \text{ mol kg}^{-1} \text{ H}_2\text{O}$ ), and  $\gamma_i$  is the activity coefficient. It should be noted that the molality basis for species activity becomes inconvenient for concentrated solutions because molality diverges to infinity as the concentration increases to the pure solute limit. Therefore, the mole fraction basis is more generally applicable for calculating activities.<sup>3</sup> Nevertheless, molality remains the most common concentration unit for aqueous systems and is used here for illustrative purposes.

Computation of  $\mu_i^0$  and  $\gamma_i$  is the central subject in electrolyte thermodynamics. Numerous methods, with various ranges of applicability, have been developed over the past several decades for their computation. Several comprehensive reviews of the available models are available (Zemaitis *et al.*,<sup>4</sup> Renon,<sup>5</sup> Pitzer,<sup>6</sup> Rafal *et al.*,<sup>7</sup> Loehe and Donohue,<sup>8</sup> Anderko *et al.*<sup>3</sup>). In the next section, the current status of modeling  $\mu_i^0$  and  $\gamma_i$  is outlined as it applies to the thermodynamics of corrosion.

### 2.38.2.1 Computation of Standard-State Chemical Potentials

The computation of the standard chemical potential  $\mu_i^0$  requires the knowledge of thermochemical data including

1. Gibbs energy of formation of species  $i$  at reference conditions (298.15 K and 1 bar).
2. Entropy or, alternatively, enthalpy of formation at reference conditions.
3. Heat capacity and volume as a function of temperature and pressure.

For numerous species, these values are available in various compilations (Chase *et al.*,<sup>9</sup> Barin and Platzki,<sup>10</sup> Cox *et al.*,<sup>11</sup> Glushko *et al.*,<sup>12</sup> Gurvich *et al.*,<sup>13</sup> Kelly,<sup>14</sup> Robie *et al.*,<sup>15</sup> Shock and Helgeson,<sup>16</sup> Shock *et al.*,<sup>17,18</sup> Stull *et al.*,<sup>19</sup> Wagman *et al.*,<sup>20</sup> and others). In general, thermochemical data are most abundant at near-ambient conditions, and their availability becomes more limited at elevated temperatures.

In the case of individual solid species, the chemical potential can be computed directly from tabulated thermochemical properties according to the standard thermodynamics.<sup>2</sup> In the case of ions and aqueous neutral species, the thermochemical properties listed above are standard partial molar properties rather than the properties of pure components. The standard partial molar properties are defined at infinite dilution in water. The temperature and pressure dependence of the partial molar heat capacity and the volume of ions and neutral aqueous species are quite complex because they are manifestations of the solvation of species, which is influenced by electrostatic and structural factors. Therefore, the computation of these quantities requires a realistic physical model.

An early approach to calculating the chemical potential of aqueous species as a function of temperature is the entropy correspondence principle of Criss and Cobble.<sup>21</sup> In this approach, heat capacities of various types of ions were correlated with the reference-state entropies of ions, thus making it

possible to predict the temperature dependence of the standard chemical potential.

A comprehensive methodology for calculating the standard chemical potential was developed by Helgeson *et al.* (Helgeson *et al.*,<sup>22</sup> Tanger and Helgeson<sup>23</sup>). This methodology is based on a semi-empirical treatment of ion solvation, and results in an equation of state for the temperature and pressure dependence of the standard molal heat capacities and volumes. Subsequently, the heat capacities and volumes are used to arrive at a comprehensive equation of state for standard molal Gibbs energy and, hence, the standard chemical potential. The method is referred to as the HKF (Helgeson–Kirkham–Flowers) equation of state. An important advantage of the HKF equation is the availability of its parameters for a large number of ionic and neutral species (Shock and Helgeson,<sup>16</sup> Shock *et al.*,<sup>18</sup> Sverjensky *et al.*<sup>24</sup>). Also, correlations exist for the estimation of the parameters for species for which little experimental information is available. The HKF equation of state has been implemented both in publicly available codes (Johnson *et al.*<sup>25</sup>) and in commercial programs. A different equation of state for standard-state properties has been developed on the basis of fluctuation solution theory (Sedlbauer *et al.*,<sup>26</sup> Sedlbauer and Majer<sup>27</sup>). This equation offers improvement over HKF for nonionic solutes and in the near-critical region. However, the HKF remains as the most widely accepted model for ionic solutes.

### 2.38.2.2 Computation of Activity Coefficients

In real solutions, the activity coefficients of species deviate from unity because of a variety of ionic interaction phenomena, including long-range Coulombic interactions, specific ion–ion interactions, solvation phenomena, and short-range interactions between uncharged and charged species. Therefore, a practically-oriented activity coefficient model must represent a certain compromise between physical reality and computational expediency.

The treatment of solution chemistry is a particularly important feature of an electrolyte model. Here, the term ‘solution chemistry’ encompasses ionic dissociation, ion pair formation, hydrolysis of metal ions, formation of metal–ligand complexes, acid–base reactions, and so on. The available electrolyte models can be grouped in three classes:

1. models that treat electrolytes on an undissociated basis,
2. models that assume complete dissociation of all electrolytes into constituent ions, and

3. speciation-based models, which explicitly treat the solution chemistry.

The models that treat electrolytes as undissociated components are analogous to nonelectrolyte mixture models. They are particularly suitable for supercritical and high temperature systems, in which ion pairs predominate. Although this approach may also be used for phase equilibrium computations at moderate conditions (e.g., Kolker *et al.*<sup>28</sup>), it is not suitable for corrosion modeling because it ignores the existence of ions. The models that assume complete dissociation are the largest class of models for electrolytes at typical conditions. Compared with the models that treat electrolytes as undissociated or completely dissociated, the speciation-based models are more computationally demanding because of the need to solve multiple reactions and phase equilibria. Another fundamental difficulty associated with the use of speciation models lies in the need to define and characterize the species that are likely to exist in the system. In many cases, individual species can be clearly defined and experimentally verified in relatively dilute solutions. At high concentrations, the chemical identity of individual species (e.g., ion pairs or complexes) becomes ambiguous because a given ion has multiple neighbors of opposite sign, and, thus, many species lose their distinct chemical character. Therefore, the application of speciation models to concentrated solutions requires a careful analysis to separate the chemical effects from physical nonideality effects.

It should be noted that, as long as only phase equilibrium computations are of interest, comparable results could be obtained with models that belong to various classes. For example, the overall activity coefficients and vapor–liquid equilibria of many transition metal halide solutions, which show appreciable complexation, can be reasonably reproduced using Pitzer's<sup>29</sup> ion-interaction approach without taking speciation into account. However, it is important to include speciation effects for modeling the thermodynamics of aqueous corrosion. This is due to the fact that the presence of individual hydrolyzed forms, aqueous complexes, and so on is often crucial for the dissolution of metals and metal oxides. It should be noted that activity coefficients of individual species are different in fully speciated models than in models that treat speciation in a simplified way. Therefore, it is important to use activity coefficients that have been determined in a fully consistent way, that is, by assuming the appropriate chemical species in the solution.

The theory of liquid-phase nonideality is well-established for dilute solutions. A limiting law for activity

coefficients was developed by Debye and Hückel<sup>30</sup> by considering the long-range electrostatic interactions of ions in a dielectric continuum. The Debye–Hückel theory predicts the activity coefficients as a function of the ionic charge and dielectric constant and density of the solvent. It reflects only electrostatic effects and, therefore, excludes all specific ionic interactions. Therefore, its range of applicability is limited to  $\sim 0.01$  M for typical systems. Several modifications of the Debye–Hückel theory have been proposed over the past several decades. The most successful modification was developed by Pitzer<sup>29</sup> who considered hard-core effects on electrostatic interactions. A more comprehensive treatment of the long-range electrostatic interactions can be obtained from the mean-spherical approximation (MSA) theory,<sup>31,32</sup> which provides a semianalytical solution for ions of different sizes in a dielectric continuum. The MSA theory results in a better prediction of the long-range contribution to activity coefficients at somewhat higher electrolyte concentrations.

The long-range electrostatic term provides a baseline for constructing models that are valid for electrolytes at concentrations that are important in practice. In most practically-oriented electrolyte models, the solution nonideality is defined by the excess Gibbs energy  $G^{\text{ex}}$ . The excess Gibbs energy is calculated as a sum of the long-range term and one or more terms that represent ion–ion, ion–molecule, and molecule–molecule interactions:

$$G^{\text{ex}} = G_{\text{long-range}}^{\text{ex}} + G_{\text{specific}}^{\text{ex}} + \cdots \quad [3]$$

where the long-range contribution is usually calculated either from the Debye–Hückel or the MSA theory, and the specific interaction term(s) represent(s) all other interactions in an electrolyte solution. Subsequently, the activity coefficients are calculated according to standard thermodynamics<sup>2</sup> as

$$\ln \gamma_i = \frac{1}{RT} \left( \frac{\partial G^{\text{ex}}}{\partial n_i} \right)_{T,P,n_{j \neq i}} \quad [4]$$

**Table 1** lists a number of activity coefficient models that have been proposed in the literature, and shows the nature of the specific interaction terms that have been adopted. In general, these models can be subdivided into two classes:

1. models for aqueous systems; in special cases, such models can also be used for other solvents as long as the system contains a single solvent;
2. mixed-solvent electrolyte models, which allow multiple solvents as well as multiple solutes.

The aqueous electrolyte models incorporate various ion interaction terms, which are usually defined

**Table 1** Summary of representative models for calculating activity coefficients in electrolyte systems

Reference	Terms	Features
<i>Aqueous (or single-solvent) electrolyte models</i>		
Debye and Hückel <sup>30</sup>	Long-range	Limiting law valid for very dilute solutions
Guggenheim <sup>33,34</sup>	Long-range + ion interaction	Simple ion interaction term to extend the Debye–Hückel limiting law; applicable to fairly dilute solutions
Helgeson <sup>35</sup>	Long-range + ion interaction	Ion interaction term to extend the limiting law; applicable to fairly dilute solutions
Pitzer <sup>29</sup>	Long-range + ion interaction	Ionic strength-dependent virial coefficient-type ion interaction term; revised Debye–Hückel limiting law; applicable to moderately concentrated solutions (~6 m)
Bromley <sup>36</sup>	Long range + ion interaction	Ionic strength dependent ion interaction term; applicable to moderately concentrated solutions (~6 m)
Zemaitis <sup>37</sup>	Long-range + ion interaction	Modification of the model of Bromley <sup>36</sup> to increase applicability range with respect to ionic strength
Meissner <sup>38</sup>	One-parameter correlation as a function of ionic strength	Generalized correlation to calculate activities based on a limited amount of experimental information
Pitzer and Simonson, <sup>39</sup> Clegg and Pitzer <sup>40</sup>	Long-range + ion interaction	Mole fraction-based expansion used for the ion interaction term; applicable to concentrated systems up to the fused salt limit
<i>Mixed-solvent electrolyte models</i>		
Chen <i>et al.</i> <sup>41</sup>	Long-range + short-range	Local-composition (NRTL) short-range term
Liu and Watanasiri <sup>42</sup>	Long-range + short-range + electrostatic solvation (Born) + ion interaction	Modification of the model of Chen <i>et al.</i> <sup>41</sup> using a Guggenheim-type ion interaction term for systems with two liquid phases
Abovsky <i>et al.</i> <sup>43</sup>	Long-range + short-range	Modification of the model of Chen <i>et al.</i> <sup>41</sup> using concentration-dependent NRTL parameters to extend applicability range with respect to electrolyte concentration
Chen <i>et al.</i> <sup>44</sup>	Long-range + short-range + ion hydration	Modification of the model of Chen <i>et al.</i> <sup>41</sup> using an analytical ion hydration term to extend applicability with respect to electrolyte concentration
Chen and Song <sup>45</sup>	Long-range + short-range + electrostatic solvation (Born)	Modification of the model of Chen <i>et al.</i> <sup>41</sup> by introducing segment interactions for organic molecules
Sander <i>et al.</i> <sup>46</sup>	Long-range + short-range	Local composition model (UNIQUAC) with concentration-dependent parameters used for short-range term
Macedo <i>et al.</i> <sup>47</sup>	Long-range + short-range	Local composition model (UNIQUAC) with concentration-dependent parameters used for short-range term
Kikic <i>et al.</i> <sup>48</sup>	Long-range + short range	Local composition group contribution model (UNIFAC) used for short-range term
Dahl and Macedo <sup>49</sup>	Short-range	Undissociated basis; no long-range contribution; group contribution model (UNIFAC) used for short-range term
Iliuta <i>et al.</i> <sup>50</sup>	Long-range + short-range	Local composition (UNIQUAC) model used for short-range term
Wu and Lee <sup>31</sup>	Extended long-range (MSA)	Mean-spherical approximation (MSA) theory used for the long-range term
Li <i>et al.</i> <sup>51</sup>	Long range + ion interaction + short range	Virial-type form used for the ion interaction term; local composition used for short-range term
Yan <i>et al.</i> <sup>52</sup>	Long-range + ion interaction + short range	Group contribution models used for both the ion interaction term and short-range term (UNIFAC)
Zerres and Prausnitz <sup>53</sup>	Long-range + short range + ion solvation	Van Laar model used for short-range term; stepwise ion solvation model
Kolker <i>et al.</i> <sup>28</sup>	Short-range	Undissociated basis; no long-range contribution
Wang <i>et al.</i> <sup>54,55</sup>	Long range + ion interaction + short range	Ionic strength-dependent virial expansion-type ion interaction term; local composition (UNIQUAC) short-range term; detailed treatment of solution chemistry
Papaiconomou <i>et al.</i> <sup>32</sup>	Extended long-range (MSA) + short-range	MSA theory used for the long-range term; local composition model (NRTL) used for the short-range term

in the form of virial-type expansions in terms of molality or mole fractions (see [Table 1](#)). Among these models, the Pitzer<sup>29</sup> molality-based model has found wide acceptance. Parameters of the Pitzer<sup>29</sup> model are available in the open literature for a large number of systems.<sup>6</sup>

The mixed-solvent electrolyte models are designed to handle a wider variety of chemistries. They invariably use the mole fraction and concentration scales. A common approach in the construction of mixed-solvent models is to use local-composition models for representing short-range interactions. The well-known local-composition models include NRTL, UNIQUAC, and its group-contribution version, UNIFAC (see Prausnitz *et al.*<sup>56</sup> and Malanowski and Anderko<sup>57</sup> for a review of these models). The local composition models are commonly used for nonelectrolyte mixtures and, therefore, it is natural to use them for short-range interactions in electrolyte systems. The combination of the long-range and local-composition terms is typically sufficient for representing the properties of moderately concentrated electrolytes in any combination of solvents. For systems that may reach very high concentrations with respect to electrolyte components (e.g., up to the fused salt limit), more complex approaches have been developed. One viable approach is to explicitly account for hydration and solvation equilibria in addition to using the long-range and short-range local composition terms (Zerres and Prausnitz,<sup>53</sup> Chen *et al.*<sup>44</sup>). A particularly effective approach is based on combining virial-type ion interaction terms with local composition models (Li *et al.*,<sup>51</sup> Yan *et al.*,<sup>52</sup> Wang *et al.*<sup>54,55</sup>). In such combined models, the local-composition term reflects the nonelectrolyte-like short-range interactions, whereas the virial-type ion interaction term represents primarily the specific ion–ion interactions that are not accounted for by the long-range contribution. These and other approaches are summarized in [Table 1](#). Among the models summarized in [Table 1](#), the models of Pitzer,<sup>29</sup> Zemaitis,<sup>37</sup> Chen *et al.*<sup>41</sup> (including their later modifications),<sup>44,45</sup> and Wang *et al.*<sup>54,55</sup> have been implemented in publicly available or commercial simulation programs.

### 2.38.2.3 Electrochemical Stability Diagrams

The  $E$ -pH diagrams, commonly referred to as the Pourbaix<sup>1</sup> diagrams, are historically the first, and remain the most important class of electrochemical stability diagrams. They were originally constructed for ideal solutions (i.e., on the assumption that  $\gamma_i = 1$ ),

which was the only viable approach at the time when they were introduced.<sup>1</sup> The essence of the procedure for generating the Pourbaix diagrams is analyzing all possible reactions between all – aqueous or solid – species that may exist in the system. The simultaneous analysis of the reactions makes it possible to determine the ranges of potential and pH at which a given species is stable. The reactions can be conveniently subdivided into two classes, that is, chemical and electrochemical reactions. The chemical reactions can be written without electrons, that is

$$\sum v_i M_i = 0 \quad [5]$$

Then, the equilibrium condition for the reaction is given in terms of the chemical potentials of individual species by

$$\sum v_i \mu_i = 0 \quad [6]$$

According to [eqn \[1\]](#), [eqn \[6\]](#) can be further rewritten in terms of species activities as

$$\sum v_i \ln a_i = -\frac{\sum v_i \mu_i^0}{RT} = \ln K \quad [7]$$

where the right-hand side of [eqn \[7\]](#) is defined as the equilibrium constant because it does not depend on species concentrations.

In contrast to the chemical reactions, the electrochemical reactions involve electrons,  $e^-$ , as well as chemical substances  $M_i$  that is

$$\sum v_i M_i + n e^- = 0 \quad [8]$$

The equilibrium state of an electrochemical reaction is associated with a certain equilibrium potential. Since electrode potential cannot be measured on an absolute basis, it is necessary to choose an arbitrary scale against which the potentials can be calculated. If a reference electrode is selected, the equilibrium state of the reaction that takes place on the reference electrode is given by an equation analogous to [eqn \[8\]](#), that is

$$\sum v_{i,\text{ref}} M_{i,\text{ref}} + n e^- = 0 \quad [9]$$

Then, the equilibrium potential  $E_0$  of [eqn \[8\]](#) is given with respect to the reference electrode as

$$E_0 - E_{0,\text{ref}} = \frac{\sum v_i \mu_i - \sum v_{i,\text{ref}} \mu_{i,\text{ref}}}{nF} \quad [10]$$

According to a generally used convention, the standard hydrogen electrode (SHE) (i.e.,  $H^+(a_{H^+} = 1)/H_2(f_{H_2} = 1)$ ) is used as a reference. The corresponding reaction that takes place on the SHE is given by

Then, eqn [10] becomes

$$E_0 - E_{0,\text{ref}} = \frac{\sum v_i \mu_i - n \left( \mu_{\text{H}^+}^0 - \frac{1}{2} \mu_{\text{H}_2}^0 \right)}{nF} \quad [12]$$

In eqn [12], the standard chemical potentials  $\mu_{\text{H}}^0$  and  $\mu_{\text{H}_2}^0$  as well as the reference potential  $E_{0,\text{ref}}$  are equal to zero at  $T = 298.15$  K. For practical calculations at temperatures other than 298.15 K, two conventions can be used for the reference electrode. According to a universal convention established by the International Union of Pure and Applied Chemistry (the ‘Stockholm convention’), the potential of SHE is arbitrarily defined as zero at all temperatures (i.e.,  $E_{0,\text{ref}} = 0$ ). When this convention is employed, eqn [12] is used as a working equation with  $E_{0,\text{ref}} = 0$ . In an alternate convention, the SHE reference potential is equal to zero only at room temperature, and its value at other temperatures depends on the actual, temperature-dependent values of  $\mu_{\text{H}^+}^0$  and  $\mu_{\text{H}_2}^0$ . In this case, it is straightforward to show (see Chen and Aral,<sup>58</sup> Chen *et al.*,<sup>59</sup>) that eqn [12] becomes

$$E_0 = \frac{\sum v_i \mu_i}{nF} \quad [13]$$

at all temperatures. Equation [13] can be further rewritten in terms of activities as

$$E_0 = \frac{\sum v_i \mu_i^0}{nF} + \frac{RT}{nF} \sum v_i \ln a_i = E_0^0 + \frac{RT}{nF} \sum v_i \ln a_i \quad [14]$$

where  $E_0^0$  is the standard equilibrium potential, which is calculated from the values of the standard chemical potentials  $\mu_i^0$ .

For a brief outline of the essence of the Pourbaix diagrams, let us consider a generic reaction in which two species, A and B, undergo a transformation. The only other species that participate in the reaction are hydrogen ions and water, that is:

If eqn [15] is a chemical reaction (i.e., if  $n = 0$ ), then its equilibrium condition (eqn [7]) can be rewritten as

$$m\text{pH} = \log \left( \frac{a_B^a}{a_A^a} \right) - \log K - \log a_{\text{H}_2\text{O}}^c \quad [16]$$

where  $\text{pH} = -\log a_{\text{H}^+}$ , and decimal rather than natural logarithms is used. For dilute solutions, it is appropriate to assume that  $a_{\text{H}_2\text{O}} = 1$ , and the last term on the right-hand side of eqn [16] vanishes. If we assume that the components A and B are aqueous dissolved species and their activities are equal, eqn [16] defines the boundary between the predominance areas of species A and B. If one of the species (A or B) is a pure

solid and the other is an aqueous species, the activity of the solid is equal to one and the activity of the aqueous species can be set equal to a certain predetermined, typically small, value (e.g.,  $10^{-6}$ ). Then, eqn [16] represents the boundary between a solid and an aqueous species at a fixed value of the dissolved species activity. Similarly, for a boundary between two pure solid phases, the activities of the species A and B are equal to one. Such a boundary is represented by a vertical line in a potential–pH space, and its location depends on the equilibrium constant according to eqn [16].

If eqn [15] represents an electrochemical reaction (i.e.,  $n \neq 0$ ), the equilibrium condition (eqn [14]) becomes

$$E_0 = E_0^0 + \frac{RT}{nF} \ln \frac{a_A^a}{a_B^b} + \frac{RT}{nF} \ln a_{\text{H}_2\text{O}} + \frac{RT \ln 10}{F} \frac{m}{n} \text{pH} \quad [17]$$

As with the chemical reactions, the term that involves the activity of water vanishes for dilute solutions, and the ratio of the activities of species A and B can be fixed to represent the boundary between the predominance areas of two species. Under such assumptions, the plot of  $E$  versus pH is a straight line with a slope determined by the stoichiometric coefficients  $m$  and  $n$ .

Thus, for each species, boundaries can be established using eqns [16] and [17]. As long as the simplifying assumptions described above are met, the boundaries can be calculated analytically. By considering all possible boundaries, stability regions can be determined using an algorithm described by Pourbaix.<sup>1</sup> Sample  $E$ –pH diagrams are shown for iron in Figure 1.

One of the main reasons for the usefulness of stability diagrams is the fact that they can illustrate the interplay of various partial processes of oxidation and reduction. The classical  $E$ –pH diagrams contain two dashed lines, labeled as ‘a’ and ‘b,’ which are superimposed on the diagram of a given metal (see Figure 1). The dashed line ‘a’ represents the conditions of equilibrium between water (or hydrogen ions) and elemental hydrogen at unit hydrogen fugacity, that is

The ‘b’ line describes the equilibrium between water and oxygen, also at unit fugacity,

Accordingly, water will be reduced to form hydrogen at potentials below line ‘a,’ and will be oxidized to form oxygen at potentials above line ‘b.’ The location

**Figure 1**  $E$ -pH (Pourbaix) diagrams for iron at 25 °C (upper diagram) and 300 °C (lower diagram). At 300 °C, the conditions of the experiments of Partridge and Hall<sup>60</sup> are superimposed on the diagram. The vertical bars show the range between the equilibrium potentials for the reduction of  $H^+$  and oxidation of Fe, thus bracketing the mixed potential in the experiments. The numbers under the bars denote the experimentally determined relative attack. The diagrams have been generated using the Corrosion Analyzer software<sup>61</sup> using the algorithm of Anderko *et al.*<sup>62</sup>

of the 'a' and 'b' lines on the diagram indicates whether a given redox couple is thermodynamically possible. For example, in the region between the line 'a' and the upper edge of the stability region of  $Fe(s)$  in Figure 1, the anodic reaction of iron oxidation can be coupled with the cathodic reaction of water or hydrogen ion reduction. In such a case, the measurable open-circuit potential of the corrosion process will establish itself between the line 'a' and the equilibrium potential for the oxidation of iron (i.e., the upper edge of the  $Fe(s)$  region). If the potential lies above

line 'a,' then water reduction is no longer a viable cathodic process, and the oxidation of iron must be coupled with another reduction process. In the presence of oxygen, reaction eqn [19] can provide such a reaction process. In such a case, the open-circuit (corrosion) potential will establish itself at a higher value for which the upper limit will be defined by line 'b.'

Pourbaix<sup>1</sup> subdivided various regions of the  $E$ -pH diagrams into three categories, that is, immunity, corrosion, and passivation. The immunity region

encompasses the stability field of elemental metals. The corrosion region corresponds to the stability of dissolved, either ionic or neutral species. Finally, passivation denotes the region in which solid oxides or hydroxides are stable. In **Figure 1**, the immunity and passivation regions are shaded, whereas the corrosion region is not. It should be noted that this classification does not necessarily reflect the actual corrosion behavior of a metal. Only immunity has a strict significance in terms of thermodynamics because in this region the metal cannot corrode regardless of the time of exposure. The stability of dissolved species in the 'corrosion' region does not necessarily mean that the metal rapidly corrodes in this area. In reality, the rate of corrosion in this region may vary markedly because of kinetic reasons. Passivation is also an intrinsically kinetic phenomenon because the protectiveness of a solid layer on the surface of a metal is determined not by its low solubility alone. The presence of a sparingly soluble solid is typically a necessary, but not sufficient condition for passivity.

Although the  $E$ -pH diagrams indicate only the thermodynamic tendency for the stability of various metals, ions, and solid compounds, they may still provide useful qualitative clues as to the expected trends in corrosion rates. This is illustrated in the lower diagram of **Figure 1**. In this diagram, the vertical bars denote the difference between the equilibrium potentials for the reduction of water and oxidation of iron. Thus, the bars indicate the tendency of the metal to corrode in deaerated aqueous solutions with varying pH. They bracket the location of the corrosion potential and, thus, indicate whether the corrosion potential will establish itself in the 'corrosion' or 'passivation' regions. The numbers associated with the bars represent the experimentally determined relative attack. It is clear that the observed relative attack is substantially greater in the regions where a solid phase is predicted to be stable than in the regions where no solid phase is predicted. Thus, subject to the limitations discussed above, the stability diagrams can be used for the qualitative assessment of the tendency of metals to corrode, and for estimating the range of the corrosion potential.

Following the pioneering work of Pourbaix and his coworkers, further refinements of stability diagrams were made to extend their range of applicability. These refinements were made possible by the progress of the thermodynamics of electrolyte solutions and alloys. Specifically, further developments focused on

1. generation of diagrams at elevated temperatures,
2. taking into account the active solution species other than protons and water molecules,
3. introduction of solution nonideality, which influences the stability of species through realistically modeled activity coefficients,
4. introduction of alloying effects by accounting for the formation of mixed oxides and the nonideality of alloy components in the solid phase, and
5. flexible selection of independent variables, other than  $E$  and pH, for the generation of diagrams.

### 2.38.2.3.1 Diagrams at elevated temperatures

The key to the construction of stability diagrams at elevated temperatures is the calculation of the standard chemical potentials  $\mu_i^0$  of all individual species as a function of temperature. In earlier studies, the entropy correspondence principle of Criss and Cobble<sup>21</sup> was used for this purpose. Macdonald and Cragnolino<sup>63</sup> reviewed the development of  $E$ -pH diagrams at elevated temperatures until the late 1980s.

The HKF equation of state<sup>22,23</sup> formed a comprehensive basis for the development of  $E$ -pH diagrams at temperatures up to 300 °C for iron, zinc, chromium, nickel, copper, and other metals (Beverkog and Puigdomenech,<sup>64-69</sup> Anderko *et al.*<sup>62</sup>) An example of a high temperature  $E$ -pH diagram is shown for Fe at 300 °C in the lower diagram of **Figure 1**. Comparison of the Fe diagrams at room temperature and 300 °C shows a shift in the predominance domains of cations to lower pH values and an expansion of the domains of metal oxyanions at higher pH values. Such effects are relatively common for metal-water systems.

### 2.38.2.3.2 Effect of multiple active species

The concept of stability diagrams can be easily extended to solutions that contain multiple chemically active species other than  $H^+$  and  $H_2O$ . In such a general case, the simple reaction **eqn [15]** needs to be extended as

where the species  $X$  and  $Y$  contain at least one common element and  $A_i$  ( $i = 1, \dots, k$ ) are the basis species that are necessary to define equilibrium equations between all species containing a given element. Reaction **eqn [20]** is normalized so that the stoichiometric coefficient for the right-hand side species ( $Y$ ) is equal to 1. Such an extension results in generalized

expressions for the boundaries between predominance regions (eqns [16] and [17]). The equilibrium expression for the chemical reactions (eqn [20] with  $v_e = 0$ ) then becomes

$$\begin{aligned}\ln K &= \left( \ln a_Y - v_X \ln a_X - \sum_{i=1}^k v_i \ln a_{A_i} \right) \\ &= \frac{1}{RT} \left( \mu_Y^0 - \mu_X^0 - \sum_{i=1}^k v_i \mu_{A_i}^0 \right) \quad [21]\end{aligned}$$

and the expression for an electrochemical reaction (eqn [20] with  $v_e \neq 0$ ) takes the form:

$$E_0 = E_0^0 + \frac{RT}{Fv_e} \left( \ln a_Y - v_X \ln a_X - \sum_{i=1}^k v_i \ln a_{A_i} \right) \quad [22]$$

Thus, the expression for the boundary lines become more complicated but the algorithm for generating the diagrams remains the same, that is, the predominance areas can still be determined semianalytically.

The strongest effect of solution species on the stability diagrams of metals is observed in the case of complex-forming ligands and species that form stable, sparingly soluble solid phases other than oxides or hydroxides (e.g., sulfides or carbonates). Several authors focused on stability diagrams for metals such as iron, nickel, or copper in systems containing sulfur species (Biernat and Robbins,<sup>70</sup> Froning *et al.*,<sup>71</sup> Macdonald and Syrett,<sup>72</sup> Macdonald *et al.*,<sup>73,74</sup> Chen and Aral,<sup>58</sup> Chen *et al.*,<sup>59</sup> Anderko and Shuler<sup>75</sup>). This is due to the importance of iron sulfide phases, which have a strong tendency to form in aqueous environments even at very low concentrations of dissolved hydrogen sulfide. The stability domains of various iron sulfides can be clearly rationalized using *E*-pH diagrams. Diagrams have also been developed for metals in brines (Pourbaix,<sup>76</sup> Macdonald and Syrett,<sup>72</sup> Macdonald *et al.*,<sup>73,74</sup> Kesavan *et al.*,<sup>77</sup> Muñoz-Portero *et al.*<sup>78</sup>). The presence of halide ions manifests itself in the stability of various metal-halide complexes. Typically, the effect of halides on the thermodynamic stability is less pronounced than the effect of sulfides. However, concentrated brines can substantially shrink the stability regions of metal oxides and promote the active behavior of metals. An example of such effects is provided by the diagrams for copper in concentrated bromide brines (Muñoz-Portero *et al.*<sup>78</sup>). Effects of formation of various carbonate and sulfate phases have also been reported (Bianchi and Longhi,<sup>79</sup> Pourbaix<sup>76</sup>).

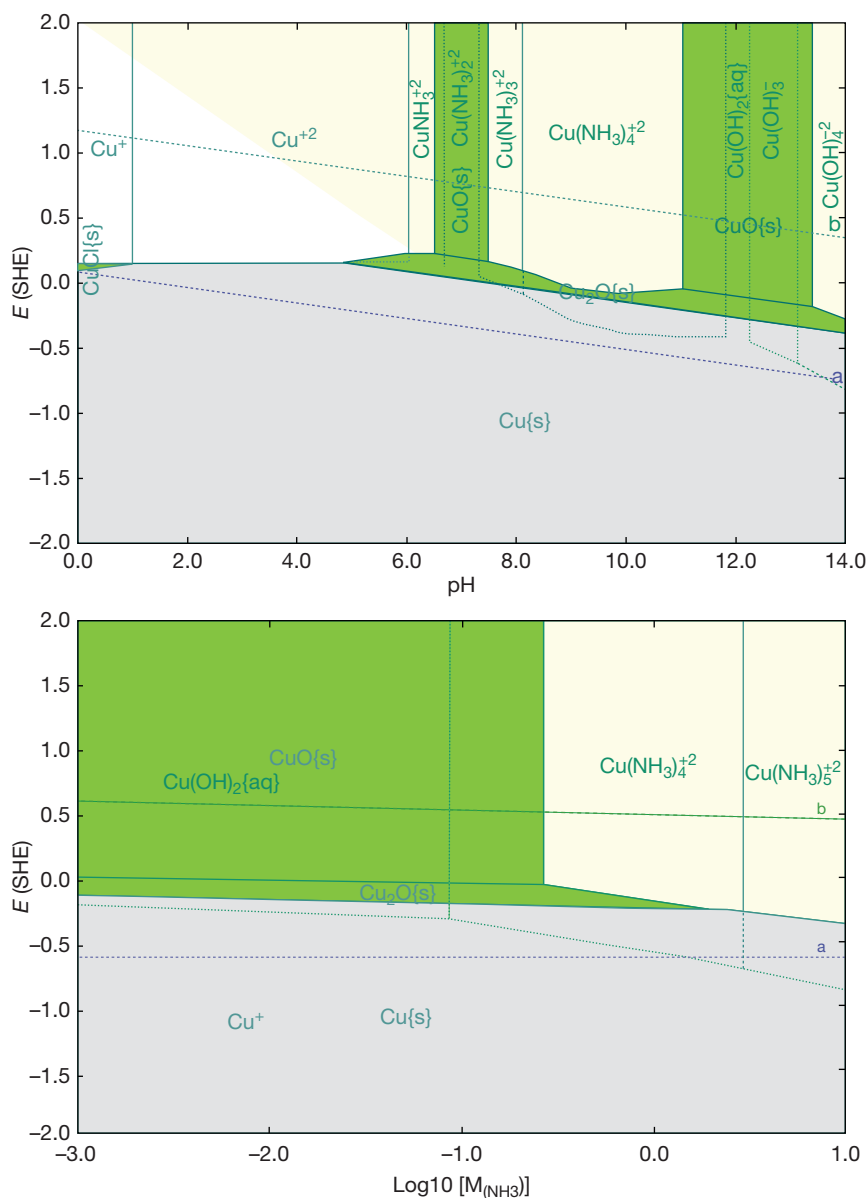

The formation of complexes of metal ions with organic ligands (e.g., chelants) frequently leads to a

significant decrease in the stability of metal oxides, which may, under some conditions, indicate an increased dissolution tendency in the passive state (Silverman,<sup>80,81</sup> Kubal and Panacek,<sup>82</sup> Silverman and Silverman<sup>83</sup>). An important example of the importance of complexation is provided by the behavior of copper and other metals in ammoniated environments. **Figure 2** (upper diagram) illustrates an *E*-pH diagram for copper in a 0.2 m NH<sub>3</sub> solution. As shown in the figure, the copper oxide stability field is bisected by the stability area of an aqueous complex. The formation of a stable dissolved complex indicates that the passivity of copper and copper-base alloys may be adversely affected in weakly alkaline NH<sub>3</sub>-containing environments. In reality, ammonia attack on copper-base alloys is observed in steam cycle environments.<sup>63</sup> Stability diagrams are a useful tool for the qualitative evaluation of the tendency of metals to corrode in such environments.

### 2.38.2.3.3 Diagrams for nonideal solutions

As long as the solution is assumed to be ideal (i.e.,  $\gamma_i = 1$  in eqn [2]), the chemical and electrochemical equilibrium expressions can be written in an analytical form, and the *E*-pH diagrams can be generated semianalytically. For nonideal solutions, the analytical character of the equilibrium lines can be preserved if fixed activity coefficients are assumed for each species (see Bianchi and Longhi<sup>79</sup>). However, such an approach does not have a general character because the activities of species change as a function of pH. This is due to the fact that, in real systems, pH changes result from varying concentrations of acids and bases, which influence the activity coefficients of all solution species. In a nonideal solution, the activities of all species are inextricably linked to each other because they all are obtained by differentiating the solution's excess Gibbs energy with respect to the number of moles of the individual species.<sup>2</sup> Therefore, in a general case, the equilibrium expressions (eqns [21] and [22]) can no longer be expressed by analytical expressions. This necessitates a modification of the algorithm for generating stability diagrams. A general methodology for constructing stability diagrams of nonideal solutions has been developed by Anderko *et al.*<sup>62</sup>

In general, the nonideality of aqueous solutions may shift the location of the equilibrium lines because the activity coefficients may vary by one or even two orders of magnitude. Such effects become pronounced in concentrated electrolyte solutions and in mixed-solvent solutions, in which water is not necessarily the predominant solvent.

**Figure 2** Use of thermodynamic stability diagrams to analyze the effect of ammonia on the corrosion of copper. The upper plot is an  $E$ -pH diagram for Cu in a 0.2 m  $\text{NH}_3$  solution. The lower plot is a potential-ammonia molality diagram.

#### 2.38.2.3.4 Diagrams for alloys

The vast majority of the published stability diagrams have been developed for pure metals. However, several studies have been devoted to generating stability diagrams for alloys, particularly those from the Fe-Ni-Cr-Mo family (Cubicciotti,<sup>84,85</sup> Beverskog and Puigdomenech,<sup>69</sup> Yang *et al.*,<sup>86</sup> Anderko *et al.*<sup>87</sup>). In general, a stability diagram for an alloy is a superposition of partial diagrams for the individual components of the alloy.<sup>69</sup> However, the partial diagrams

are not independent because the alloy components form a solid solution and, therefore, their properties are linked. The superposition of partial diagrams makes it possible to analyze the tendency of alloy components for preferential dissolution. This may be the case when a diagram indicates that one alloy component has a tendency to form a passivating oxide, whereas another component has a tendency to form ions. Also, stability diagrams indicate in a simple way which alloy component is more anodic.

There are two key effects of alloying on thermodynamic equilibrium, that is, the formation of mixed solid corrosion products and the nonideality of alloy components in the solid phase. The formation of mixed solid corrosion products may be particularly significant for passive systems. Fe–Ni–Cr alloys may form mixed oxides, including  $\text{NiFe}_2\text{O}_4$ ,  $\text{FeCr}_2\text{O}_4$ , and  $\text{NiCr}_2\text{O}_4$ . Such oxides may be more stable than the single oxides of chromium, nickel, and iron, which appear in stability diagrams for pure metals.  $E$ –pH diagrams that include mixed oxide phases have been reported by Cubicciotti,<sup>84,85</sup> Beverskog and Puigdomenech,<sup>69</sup> and Yang *et al.*<sup>86</sup> for Fe–Ni–Cr alloys in ideal aqueous solutions.

Another fundamental effect of alloying on the thermodynamic behavior results from the nonideality of the solid solution phase. In contrast to pure metals, the activity of a metal in an alloy is no longer equal to 1. This affects the value of the equilibrium potential for metal dissolution, which determines the upper boundary of the stability field of an alloy component on an  $E$ –pH diagram. As with the liquid phase, the activity of solid solution components can be obtained from a comprehensive excess Gibbs energy model of the solid phase. Thermodynamic modeling of alloys is a very wide area of research, which is beyond the scope of this chapter (see Lupis<sup>88</sup> and Saunders and Miodownik<sup>89</sup> for reviews). Detailed models have been developed for the thermodynamic behavior of alloys on the basis of high temperature data that are relevant to metallurgical processes. These models can be, in principle, extrapolated to lower temperatures that are of interest in aqueous corrosion. Despite the inherent uncertainties associated with extrapolation, estimates of activities of alloy components can be obtained in this way and incorporated into the calculation of stability diagrams. Such an approach was used by Anderko *et al.*<sup>87</sup> in a study in which solid solution models were coupled with an algorithm for generating stability diagrams for Fe–Ni–Cr–Mo–C and Cu–Ni alloys. In that work, the solid solution models of Hertzman,<sup>90</sup> Hertzman and Jarl,<sup>91</sup> and Anderson and Lange<sup>92</sup> were implemented to estimate the activities of alloy components.

It should be noted that the effect of varying activities of alloy components on  $E$ –pH diagrams is relatively limited. This is due to the fact that alloy phase nonideality, while crucial for modeling alloy metallurgy, is only a secondary contribution to the energetics of reactions between metals and aqueous species. The effect of alloy solution nonideality manifests itself in a limited shift of the upper boundary of

the metal stability area in  $E$ –pH diagrams. The effect of mixed oxide phases is usually much more pronounced on stability diagrams.

### 2.38.2.3.5 Potential–concentration diagrams

Once the thermodynamic treatment of solution chemistry is extended to allow for the effect of species other than  $\text{H}^+$  and  $\text{H}_2\text{O}$  (see eqns [21] and [22]), other independent variables become possible in addition to  $E$  and pH. The chemical and electrochemical boundaries can then be calculated as a function of concentration variables other than pH. In particular, the stability diagrams can be generated as a function of the concentration of active solution species that may react with metals through precipitation, complexation, or other reactions. Thus, an extension of  $E$ –pH diagrams to  $E$ –species concentration diagrams is relatively straightforward. The algorithm developed by Anderko *et al.*<sup>62</sup> for nonideal solutions is equally applicable to  $E$ –pH and  $E$ –concentration diagrams. An example of such a diagram is provided in the lower plot of Figure 2. This plot is an  $E$ – $\text{NH}_3$  molality diagram and illustrates the thermodynamic behavior of copper when increasing amounts of ammonia are added to an aqueous environment. In this simulation, pH varies with ammonia concentration. However, pH is less important in this case than the concentration of  $\text{NH}_3$  because the stability of copper oxide is controlled by the formation of copper–ammonia complexes. The diagram indicates at which concentration of ammonia the copper oxide film becomes thermodynamically unstable, thus increasing the tendency for metal dissolution.

### 2.38.2.4 Chemical Equilibrium Computations

While the  $E$ –concentration diagrams are merely an extension of Pourbaix's original concept of stability diagrams, a completely different kind of thermodynamic analysis can also be performed using electrolyte thermodynamics. This kind of analysis relies on solving the chemical equilibrium expressions without using the potential as an independent variable. Assuming that temperature, pressure, and starting amounts of components (both metals and solution species) are known, the equilibrium state of the system of interest can be found by simultaneously solving the following set of equations:

1. chemical equilibrium equations (eqn [6]) for a linearly independent set of reactions that link all the species that exist in the system; this set of

- equations also includes solid–liquid equilibrium reactions (or precipitation equilibria);
2. if applicable, vapor–liquid and, possibly, liquid–liquid equilibrium equations (i.e., the equality of chemical potentials of species in coexisting phases),
  3. material balance equations for each element in the system, and
  4. electroneutrality balance condition.

Once the solution is found, the potential can be calculated using the Nernst equation for any redox pair in the equilibrated system. It should be noted that procedures for solving these equations are very involved and require sophisticated numerical techniques. Methods for solving such electrolyte equilibrium problems were reviewed by Zemaitis *et al.*<sup>4</sup> and Rafal *et al.*,<sup>7</sup> and will not be discussed here.

The solution of the chemical equilibrium conditions provides detailed information about the thermodynamically stable form(s) of the metal in a particular system. This is in contrast with the information presented on the  $E$ –pH diagrams, which essentially indicate whether a given oxidation reaction (e.g., dissolution of a metal) can occur simultaneously with a given reduction reaction (e.g., reduction of water). In the chemical equilibrium algorithm outlined above, all possible reduction and oxidation equilibria are solved simultaneously. This provides very detailed information about the chemical identity of all species and their concentrations. On the other hand, this kind of information is less

conductive to gaining qualitative insight into the key anodic and cathodic reactions that occur in the system.

To visualize the information obtained from detailed chemical equilibrium computations, stability diagrams can be constructed by selecting key independent variables. Such diagrams can be referred to as ‘chemical’ as opposed to ‘electrochemical’ because they do not involve the potential as an independent variable. An example of such a diagram is shown in **Figure 3**, which shows the stability areas of solid corrosion products of iron as a function of the amount of dissolved iron and hydrogen sulfide in 1 kg of water. Diagrams of this type can be generated by repeatedly solving the chemical equilibrium expressions outlined above and tracing the stability boundaries of various species (Lencka *et al.*,<sup>94</sup> Sridhar *et al.*<sup>93</sup>). Such diagrams are useful for illustrating the transition between various corrosion products (e.g., iron sulfide and magnetite in **Figure 3**) as a function of environmental conditions. Diagrams of this kind have been generated by Sridhar *et al.*<sup>95</sup> to identify the conditions under which  $\text{FeCO}_3$ ,  $\text{Fe}_3\text{O}_4$ , and  $\text{Fe}_2\text{O}_3$  coexist as corrosion products of carbon steel. This approach was used to elucidate conditions that are conducive to intergranular stress corrosion cracking in weakly alkaline carbonate systems, which has been associated with the transition between iron carbonate, iron (II), and iron (III) corrosion products.

It should be noted that simplified ‘chemical’ diagrams can be generated using activities rather than

**Figure 3** Stability diagram for solid iron corrosion products as a function of the molality of dissolved Fe and the total number of moles of  $\text{H}_2\text{S}$  per 1 kg of  $\text{H}_2\text{O}$ . The diagram has been constructed by computing the equilibrium states of solid–liquid–vapor reactions.<sup>93</sup>

concentrations of species as independent variables. Such an approach makes it possible to obtain the 'chemical' diagrams in a semianalytical way, as with the classical Pourbaix diagrams. An example of such diagrams is provided by Mohr and McNeil<sup>96</sup> for the Cu–H–O–Cl system. However, such simplified 'chemical' diagrams suffer from the fundamental disadvantage that species activities are not directly measurable and are, therefore, much less suitable as independent variables than concentrations. Comprehensive 'chemical' diagrams can be obtained only by simultaneously solving the chemical and phase equilibrium expressions for each set of conditions, preferably with the help of a realistic model for liquid-phase activity coefficients.

### 2.38.2.5 Problems of Metastability

The main strength of the stability diagrams lies in their purely thermodynamic nature. Accordingly, they can be generated using equilibrium thermochemical properties that are obtained from a variety of classical experimental sources (e.g., solubility, vapor pressure, calorimetric or electromotive force measurements for bulk systems) without recourse

to any electrochemical kinetic studies of surfaces. At the same time, the purely thermodynamic nature of the diagrams is also their main weakness. An important limitation of the stability diagrams is the fact that they predict the equilibrium phases, whereas the actual corrosion behavior may be controlled by metastable phases. The same limitation applies to the detailed thermodynamic computations outlined earlier.

To illustrate the problems of metastability, it is instructive to examine how  $E$ –pH diagrams can be used to rationalize the Faraday paradox of iron corrosion in nitric acid, which historically played a great role in establishing the concept of passivity (Macdonald<sup>97</sup>). Faraday's key observation was that iron easily corroded in dilute nitric acid with the evolution of hydrogen. However, it did not corrode with an appreciable rate in concentrated  $\text{HNO}_3$  solutions despite their greater acidity. When scratched in the solution, an iron sample would corrode for a short time and, then, rapidly passivate. A stability diagram for this system is shown in Figure 4. This figure presents a superposition of an  $E$ –pH diagram for iron species and another one for nitrogen species. Dilute nitric acid is a weak oxidizing agent and, therefore, the main cathodic reaction in this case is

**Figure 4** Metastability on the  $E$ –pH diagram and the interpretation of the Faraday paradox of iron corrosion in dilute and concentrated nitric acid. The stability fields of the oxides ( $\text{Fe}_3\text{O}_4$  and  $\text{Fe}_2\text{O}_3$ ) are extended into the metastable region (long dashed lines). An  $E$ –pH diagram for nitrogen is superimposed on the diagram for Fe. The line 'c' is a metastable equilibrium line for the reduction of  $\text{HNO}_3$  to  $\text{HNO}_2$ . The ovals marked as 'concentrated  $\text{HNO}_3$ ' and 'dilute  $\text{HNO}_3$ ' indicate the mixed potential ranges that are expected for iron in concentrated and dilute  $\text{HNO}_3$ , respectively.

the common reaction of reduction of  $H^+$  ions. The equilibrium potential for this reaction is given by the dotted line marked as 'a' in the diagram. The anodic process is the oxidation of Fe, for which the equilibrium potential is given by the equilibrium line between Fe(s) and  $Fe^{2+}$  in the diagram. Thus, the corrosion potential will establish itself between the 'a' line and the upper limit of the stability field of elemental iron. This corrosion potential range is approximately shown by the lower ellipsoid in **Figure 4**. In this region, the stable iron species is  $Fe^{2+}$  and, therefore, the stability diagram predicts the dissolution of iron with the formation of  $Fe^{2+}$  ions. Unlike dilute nitric acid, concentrated  $HNO_3$  is a strong oxidizing agent. The main reduction reaction in this case is

The equilibrium potential for this reaction is shown by a line marked as 'c' in **Figure 4**. It should be noted that the nitrite ions ( $NO_2^-$ ) are metastable and, therefore, a stability field of nitrites does not appear on an  $E$ -pH diagram of nitrogen. Nevertheless, the equilibrium potential for reaction eqn [21] can be easily calculated as described above. It lies within the stability field of elemental nitrogen  $N_2(aq)$ . The corrosion potential will then establish itself at a much higher potential, relatively close to the dominant cathodic line 'c.' The likely location of the corrosion potential is outlined in **Figure 4** by an ellipsoid marked 'concentrated  $HNO_3$ .' However, the stable species in this region are the  $Fe^{2+}$  and  $Fe^{3+}$  ions. Thus, the stability diagram does not explain the Faraday paradox as long as only stable species are considered. As indicated by Macdonald,<sup>97</sup> the  $E$ -pH diagram becomes consistent with experimental observation when the existence of metastable phases is allowed for. The dashed lines in **Figure 4** show the metastable extensions of the  $Fe^{2+}/Fe_3O_4$  and  $Fe_3O_4/Fe_2O_3$  equilibrium lines into the acidic range. Thus, it is clear that the corrosion potential of iron in concentrated  $HNO_3$  is likely to establish itself in a potential range in which metastable iron oxides are stable. In contrast, the metastable solids are not expected to form at the low potentials that correspond to dilute  $HNO_3$  environments (i.e., below the  $Fe^{2+}$ /metastable  $Fe_3O_4$  boundary). If the surface is scratched, the large supply of  $H^+$  ions near the scratch will create conditions under which the potential will be below the 'a' line and short-term hydrogen evolution will follow. However, this will lead to a rapid depletion of the  $H^+$  ions, and the potential will shift to higher values, at which metastable phases can lead to passivation.

The formation of metastable solid phases is fairly common. The metastability of chromium oxide phases is important for the passivity of Fe-Ni-Cr alloys in acidic solutions. Although the  $E$ -pH diagrams indicate that chromium oxides/hydroxides cease to be stable in relatively weakly acidic solutions, the practical passivity range extends to a more acidic range for numerous alloys. Also, the metastability of iron sulfide phases plays an important role in the behavior of corrosion products in  $H_2S$  containing environments. Anderko and Shuler<sup>75</sup> used stability diagrams to evaluate the natural sequence of formation of various iron sulfide phases (e.g., amorphous FeS, mackinawite, pyrrhotite, greigite, marcasite, or pyrite). The sequence of formation of such phases could be predicted on the basis of the simple but reasonably accurate rule that the order of formation of solids is the inverse of the order of their thermodynamic stability. Stability diagrams are then used to predict the conditions under which various metastable phases are likely to form.

Thermodynamics provides a convenient starting point in the simulation of aqueous corrosion. Although it is inherently incapable of predicting the rates of interfacial phenomena, it is useful for predicting the final state toward which the system should evolve if it is to reach equilibrium. Furthermore, the computation of the final, thermodynamic equilibrium state can be refined by taking into account the metastable phases. In addition to determining the equilibrium state in metal-environment systems, electrolyte thermodynamics provides information on the properties of the environment. Such information, including speciation in the liquid phase, concentrations and activities of individual species, and phase equilibria, is necessary for constructing kinetic models of corrosion.

### 2.38.3 Modeling the Kinetics of Aqueous Corrosion

Aqueous corrosion is intrinsically an electrochemical process that involves charge transfer at a metal-solution interface. Because aqueous corrosion is a heterogeneous process, it involves the following fundamental steps:

1. reactions in the bulk aqueous environment,
2. mass transport of reactants to the surface,
3. charge transfer reactions at the metal surface,
4. mass transport of reaction products from the surface, and
5. reactions of the products in the bulk environment.

Reactions in the bulk environment (1 and 5) can be considered, with some important exceptions, to be equilibrium. As long as they are treated as equilibrium phenomena, they remain within the domain of electrolyte thermodynamics. On the other hand, the charge transfer reactions at the surface (3), and their coupling with mass transport (2 and 4) require the tools of electrochemical kinetics. In this section, we review the fundamentals of modeling approaches to electrochemical kinetics.

The objective of modeling the kinetics of aqueous corrosion is to relate the rate of electrochemical corrosion to external conditions (e.g., environment composition, temperature, and pressure), flow conditions, and the chemistry and metallurgical characteristics of the corroding interface. The two main quantities that can be obtained from electrochemical modeling are the corrosion rate ( $v_{\text{corr}}$  often expressed as the corrosion current density  $i_{\text{corr}}$ ) and corrosion potential ( $E_{\text{corr}}$ ). For practical applications, the calculation of the corrosion rate is of primary interest for simulating general corrosion and the rate of dissolution in occluded environments such as pits or crevices. The value of the corrosion potential ( $E_{\text{corr}}$ ) is also of interest because there is often a relationship between the value of the corrosion potential and the type of corrosion damage that occurs. In general, if the corrosion potential is above a certain critical potential ( $E_{\text{crit}}$ ), a specific form of corrosion that is associated with  $E_{\text{crit}}$  can occur, typically at a rate that is determined by the difference  $E_{\text{corr}} - E_{\text{crit}}$ . This general observation applies to localized corrosion including pitting, crevice corrosion, intergranular stress corrosion cracking, and so on. An internally consistent model for general corrosion should simultaneously provide reasonable values of the corrosion rate and corrosion potential. Thus, the computation of the corrosion potential is of interest not so much for modeling general corrosion but for predicting other forms of corrosion.

### 2.38.3.1 Kinetics of Charge-Transfer Reactions

The theory of charge-transfer reactions is well developed and has been reviewed in detail by a number of authors including Vetter,<sup>98</sup> Bockris and Reddy,<sup>99</sup> Kaesche,<sup>100</sup> Bockris and Khan,<sup>101</sup> and Gileadi.<sup>102</sup> Here, we summarize the key relationships that form the basis of modeling.

Considering a simple reaction of transfer of  $n$  electrons between two species, a reduced form ‘Red’

and an oxidized form ‘Ox’:

the current density associated with this reaction is, according to Faraday’s law, equal to the difference between the anodic rate  $v_a$  and the cathodic rate  $v_c$ , multiplied by  $nF$ :

$$i = nF(v_a - v_c) \quad [25]$$

According to the theory of electrochemical kinetics,<sup>98</sup> the rates of the anodic and cathodic reactions are related to the potential and the concentrations of the reacting species at the phase boundary, that is

$$i_a = nFv_a = nFk_a c_{r,s}^{x,r} \exp\left(\frac{\alpha_a nFE}{RT}\right) \quad [26]$$

$$i_c = -nFv_c = -nFk_c c_{o,s}^{x,o} \exp\left(-\frac{\alpha_c nFE}{RT}\right) \quad [27]$$

where  $k_a$  and  $k_c$  are the anodic and cathodic rate constants,  $\alpha_a$  and  $\alpha_c$  are the anodic and cathodic electrochemical transfer coefficients,  $c_{r,s}$  and  $c_{o,s}$  are the concentrations of the reduced (r) and oxidized (o) forms at the surface, respectively, and  $x,r$  and  $x,o$  are the reaction orders with respect to the reduced and oxidized species. For a given individual redox process, the anodic and cathodic electrochemical transfer coefficients are interrelated as  $\alpha_c = 1 - \alpha_a$ . The total current density for reaction eqn [24] is then

$$i = nFk_a c_{r,s}^{x,r} \exp\left(\frac{\alpha_a nFE}{RT}\right) - nFk_c c_{o,s}^{x,o} \exp\left(-\frac{\alpha_c nFE}{RT}\right) \quad [28]$$

At the equilibrium (reversible) potential  $E_0$ , the current density  $i$  is equal to zero. In the absence of a net current, the concentrations of the species at the surface are equal to their bulk concentrations (i.e.,  $c_{r,s} = c_{r,b}$  and  $c_{o,s} = c_{o,b}$ ). Then, the current density of the anodic process is equal to that of the anodic process and is defined as the exchange current density  $i_0$ , that is,

$$i_0 = nFk_a c_{r,b}^{x,r} \exp\left(\frac{\alpha_a nFE_0}{RT}\right) = nFk_c c_{o,b}^{x,o} \exp\left(-\frac{\alpha_c nFE_0}{RT}\right) \quad [29]$$

Using eqn [29], the equation for the current density [28] can be expressed in terms of the exchange current density and the overvoltage  $\eta = E - E_0$ :

$$i = i_0 \left(\frac{c_{r,s}}{c_{r,b}}\right)^{x,r} \exp\left(\frac{\alpha_a nF(E - E_0)}{RT}\right) - i_0 \left(\frac{c_{o,s}}{c_{o,b}}\right)^{x,o} \exp\left(-\frac{\alpha_c nF(E - E_0)}{RT}\right) \quad [30]$$

The ratios  $c_{r,s}/c_{r,b}$  and  $c_{o,s}/c_{o,b}$  depend on the transport of reactants and products to and from the corroding interface. If the mass transport is slow compared to charge transfer, the surface concentrations become different from those in the bulk. Conversely, if charge transfer is slow relative to mass transfer, the reaction is under charge transfer control and the ratios are equal to one not only at the equilibrium potential. In such a case, eqn [30] takes a particularly simple form and is usually referred to as the Butler–Volmer equation for charge-transfer reactions:

$$i = i_0 \exp\left(\frac{\alpha_a nF(E - E_0)}{RT}\right) - i_0 \exp\left(-\frac{\alpha_c nF(E - E_0)}{RT}\right) \quad [31]$$

The electrochemical transfer coefficient  $\alpha$  depends on the mechanism of the charge transfer reaction. For some reactions, its value can be deduced from mechanistic considerations. However, in many cases, it needs to be determined empirically. It can be determined in the form of empirical Tafel coefficients defined as the slope of a plot of potential against the logarithm of current density, that is

$$\beta_a = \frac{dE}{d \ln i_a}; \quad \beta_c = \frac{dE}{d \ln i_c} \quad [32]$$

which yields

$$\beta_a = \frac{RT}{\alpha_a nF}; \quad \beta_c = \frac{RT}{\alpha_c nF} \quad [33]$$

or, in a more traditional decimal logarithm form:

$$b_a = \frac{2.303RT}{\alpha_a nF}; \quad b_c = \frac{2.303RT}{\alpha_c nF} \quad [34]$$

Then, the Tafel coefficients  $b_a$  or  $b_c$  can be used in eqns [28] or [30] instead of the electrochemical transfer coefficient.

The above formalism includes both the cathodic and anodic process for a particular redox couple. However, in practical corrosion modeling, it is usually entirely sufficient to include only either a cathodic or an anodic partial current for a given redox process. Specifically, the cathodic partial process can be neglected for metal-ion reactions because the deposition of metal ions (i.e., the reverse of metal dissolution) is typically not of practical significance in corrosion. Similarly, the anodic partial process can be usually neglected for oxidizing agents because it is only their reduction that is of interest for corrosion. There are some exceptions to this rule, for example, in the case of relatively noble metals whose ions can be reduced under realistic conditions. Nevertheless, in the remainder of this review, we will separately consider partial anodic and cathodic processes for corrosion-related reactions.

As mentioned above, the concentrations of reactants and products at the surface depend on the mass transport to and from the corroding interface. In general, three mechanisms contribute to mass transport, that is, diffusion, migration, and convection. In many practical applications, migration can be neglected. This is the case for the transport of neutral molecules in any environment and, also, for the transport of charged species in environments that contain appreciable amounts of background electrolytic components (e.g., as supporting electrolyte). Migration becomes important in ionic systems in which there is no supporting electrolyte. We will return to the treatment of migration later in this review. If migration is neglected, the treatment of mass transfer by diffusion and convection can be simplified by using the concept of the Nernst diffusion layer. According to this concept, the environment near the corroding surface can be divided into two regions. In the inner region, called the Nernst diffusion layer, convection is negligible and diffusion is the only mechanism of transport. In the outer region, concentrations are considered to be uniform and equal to those in the bulk solution. Thus, the concentration changes linearly from the surface concentration to the bulk concentration over a distance  $\delta$ , which is the thickness of the diffusion layer. In such a model, the flux of a species  $i$  in the vicinity of a corroding interface is given by Fick's law

$$\mathcal{J}_i = -D_i \left( \frac{\partial c_i}{\partial z} \right)_{z=0} \quad [35]$$

where  $D_i$  is the diffusion coefficient of species  $i$  and  $z$  in the direction perpendicular to the surface. Integration of eqn [35] over the thickness of the diffusion layer gives:

$$\mathcal{J}_i = -D_i \frac{c_{i,b} - c_{i,s}}{\delta_i} \quad [36]$$

It should be noted that the diffusion layer thickness  $\delta$  is not a general physical property of the system. Rather, it is a convenient mathematical construct that makes it possible to separate the effects of diffusion and convection. It depends on the flow conditions, properties of the environment, and the diffusion coefficient of individual species. Thus, it may be different for various species. Methods for calculating  $\delta$  will be outlined later in this review. Equation [36] can be applied to both the reactants that enter into electrochemical reactions at the interface and to corrosion products that leave the interface. Then, it can be combined with Faraday's law to obtain the current

density. For an oxidant  $o$ , eqn [36] yields an expression for a cathodic partial current density:

$$i_c = nF\mathcal{J}_o = -nFD_o \frac{c_{o,b} - c_{o,s}}{\delta_o} \quad [37]$$

According to eqn [37], the current density reaches a maximum, limiting value when the surface concentration  $c_{o,s}$  decreases to zero. This condition defines the limiting current density, that is

$$i_{c,L} = -\frac{nFD_o c_{o,b}}{\delta_o} \quad [38]$$

For a corrosion product (e.g., Me ions), an analogous equation can be written for an anodic current density

$$i_a = nF\mathcal{J}_{Me} = -nFD_{Me} \frac{c_{Me,b} - c_{Me,s}}{\delta_{Me}} \quad [39]$$

In eqn [39], the surface concentration is typically limited by the solubility of corrosion products. Thus, a limiting anodic current density can be reached when the surface concentration of metal ions corresponds to the metal solubility, that is

$$i_{a,L} = -nFD_{Me} \frac{c_{Me,b} - c_{Me,sat}}{\delta_{Me}} \quad [40]$$

Combination of eqns [26]–[28] for charge-transfer processes and the simplified mass-transport equations (eqns [37] and [39]) yields a general formalism for electrochemical processes that are influenced by both charge transfer and mass transport. For example, for a cathodic process, the current density obtained from eqn [37] is equal to that obtained from eqn [27]. Thus, the surface concentration of the diffusing species can be obtained from eqn [37] and substituted into eqn [27]. The resulting equation can be solved analytically for  $i_c$  for some values of the reaction order  $x_o$ . If the reaction order is equal to one (i.e.,  $x_o = 1$  in eqn [27]), a particularly simple relationship is obtained for  $i_c$ , that is

$$\frac{1}{i_c} = \frac{1}{i_{c,ct}} + \frac{1}{i_{c,L}} \quad [41]$$

where  $i_{c,L}$  is the limiting current density (eqn [38]) and  $i_{c,ct}$  is the charge-transfer contribution to the current density. The latter quantity is given by eqn [27] with the bulk concentration  $c_{o,b}$  replacing the surface concentration, that is

$$i_c = -nFk_c c_{o,b}^{x_o} \exp\left(-\frac{\alpha_c nFE}{RT}\right) \quad \text{with } x_o = 1 \quad [42]$$

An analytical formula can also be obtained when  $x_o = 0.5$ .<sup>103</sup> For an arbitrary value of the reaction

order, the current density can be computed numerically by solving a single equation.

It should be noted that eqns [26] and [27] are particularly simple forms for reactions of the type [24], in which no species other than *Red* and *Ox* participate. In general, the preexponential part of eqns [26] and [27] depends on the mechanism of a particular electrochemical reaction. In general, the preexponential terms of eqns [26] and [27] can be generalized using the surface coverage factors,  $\theta_i$ , for reactive species that participate in electrochemical processes, that is,

$$i_a = nFk_a \theta_1^{x_1} \theta_2^{x_2} \dots \theta_m^{x_m} \exp\left(\frac{\alpha_a nFE}{RT}\right) \quad [43]$$

$$i_c = -nFk_c \theta_1^{x_1} \theta_2^{x_2} \dots \theta_m^{x_m} \exp\left(-\frac{\alpha_c nFE}{RT}\right) \quad [44]$$

The surface coverage factors,  $\theta_i$ , are further related to the concentrations (or, more precisely, activities) of individual species at the metal surface through appropriate adsorption isotherms. In general, analysis of reaction mechanisms on the basis of experimental data leads to a substantial simplification of eqns [43] and [44]. In many cases, activities of species can be directly used in the kinetic expressions rather than the surface coverage fractions.

The above formalism makes it possible to set up a model of electrochemical kinetics on a corroding metal surface by considering the following steps:

1. determining all possible partial cathodic and anodic processes that may occur in a given metal-environment combination;
2. writing equations for the partial cathodic or anodic current densities associated with charge transfer reactions (eqns [43] and [44] or simplifications thereof); and
3. writing equations for the mass transport of the species that participate in the charge-transfer reactions (eqns [37] and [39]). In some simple, but realistic cases a combination of the charge-transfer and mass-transport equations results in analytical formulas such as eqn [41] for partial electrochemical processes.

Once the equations for the partial anodic and cathodic processes are established, the behavior of a corroding surface can be modeled on the basis of the Wagner–Traud<sup>104</sup> theory of metallic corrosion, often referred to as the mixed potential theory. According to the mixed potential theory, the sum of all partial anodic currents is equal to the sum of all cathodic

currents. Further, it is assumed that the electrical potential of the metal at an anodic site is equal to that at a cathodic site. These assumptions follow from the requirement that charge accumulation within a metal cannot occur and, therefore, the electrons produced as a result of oxidation processes must be consumed in the reduction processes. Therefore, in a freely corroding system, we have

$$\sum_j A_a i_{a,j} + \sum_j A_c i_{c,j} = 0 \text{ at } E = E_{\text{corr}} \quad [45]$$

where  $A_a$  and  $A_c$  are the areas over which the anodic and cathodic reactions occur, respectively. The first sum in eqn [45] enumerates all anodic partial reactions and the second sum pertains to all cathodic reactions. Equation [45] is written using the sign conventions introduced earlier, in which the cathodic processes are written with a negative sign.

Equation [45] can be solved to obtain the corrosion potential,  $E_{\text{corr}}$ . Then, the corrosion current density and, equivalently, the corrosion rate, can be computed from the anodic current density for metal dissolution at the corrosion potential, that is

$$i_{\text{corr}} = i_{a,\text{Me}}(E_{\text{corr}}) \quad [46]$$

At potentials that deviate from the corrosion potential, the left-hand side of eqn [45] represents the predicted current. Such a computed current versus potential relationship can be compared with experimentally determined polarization behavior.

In the case of general corrosion,  $A_a = A_c$  and the solution of eqns [45] and [46] yields the corrosion potential and general corrosion rate. For localized corrosion, there is usually a great disparity between the areas on which the anodic and cathodic processes operate.

### 2.38.3.2 Modeling Adsorption Phenomena

Before discussing partial electrochemical reactions, it is necessary to outline the treatment of adsorption because the presence of adsorbed species is frequently assumed to derive expressions for electrochemical processes.

Adsorption of neutral molecules and ions on metals has been reviewed in detail by Gileadi,<sup>105</sup> Damaskin *et al.*,<sup>106</sup> and Habib and Bockris.<sup>107</sup> In general, adsorption leads to the reduction of the surface area that is accessible to electrochemical reactions. In such cases, adsorption results in a reduction in the rate of both anodic and cathodic processes. Thus, the rates of electrochemical reactions become modified

by the factor  $(1 - \sum \theta_j)$ , in which  $\theta_j$  is a coverage fraction by species  $j$ . At the same time, adsorption may result in the formation of surface complexes that have different dissolution characteristics. An example of such a dual effect is provided by halide ions on Fe-group metal surfaces corroding in the active state. At relatively low or moderate halide concentrations, adsorption of halides leads to a reduction in electrochemical reaction rates. However, at higher halide concentrations, the adsorbed halide ions interfere with the mechanism of anodic dissolution of iron, which may lead to an increase in the corrosion rate.

A general formalism for modeling the effect of adsorption on electrochemical reactions is provided by the Frumkin isotherm. The Frumkin formalism takes into account the interactions between the species adsorbed on the surface. It results from the requirement that the rate of adsorption is equal to the rate of desorption in the stationary state,<sup>105</sup> that is

$$v_{\text{ads},i} = v_{\text{des},i} \quad [47]$$

where the subscript  $i$  denotes any adsorbable species. The rate of adsorption is given by

$$v_{\text{ads},i} = k_{\text{ads},i} \left( 1 - \sum_j \theta_j \right) a_i \exp \left( -\beta \sum_j A_{ij} \theta_j \right) \quad [48]$$

where  $k_{\text{ads},i}$  is an adsorption rate constant,  $\theta_i$  is a fraction of the surface covered by species  $i$ ,  $a_i$  is the activity of species  $i$  in the solution,  $\beta$  is a transfer coefficient, and  $A_{ij}$  is a surface interaction coefficient between species  $i$  and  $j$ . The first term in parentheses on the right-hand side of eqn [48] represents the available surface, and the second term represents the effect of pairwise interactions between adsorbed species. The rate of desorption is given by

$$v_{\text{des},i} = k_{\text{des},i} \theta_i \exp \left( (1 - \beta) \sum_j A_{ij} \theta_j \right) \quad [49]$$

where  $k_{\text{des},i}$  is the desorption rate constant. Combination of eqns [48] and [49] yields the Frumkin isotherm, that is

$$K_{\text{ads},i} a_i = \frac{k_{\text{ads},i}}{k_{\text{des},i}} a_i = \frac{\theta_i}{1 - \sum_j \theta_j} \exp \left( \sum_j A_{ij} \theta_j \right) \quad [50]$$

where  $K_{\text{ads},i}$  is an adsorption equilibrium constant. Equation [50] can be simplified if it is assumed that the species are independently adsorbed. Then, the interactions between the species become zero, and eqn [50] takes the form of the well-known Langmuir isotherm:

$$K_{\text{ads},i}a_i = \frac{\theta_i}{1 - \sum_j \theta_j} \quad [51]$$

The Langmuir isotherm is extensively used in electrochemical kinetics. The Frumkin isotherm has been used in some studies when more accurate modeling of adsorption is warranted by experimental data, for example, in the case of corrosion in very concentrated brines (Anderko and Young<sup>108</sup>).

It should be noted that detailed modeling of adsorption requires taking into account the effect of potential on adsorption. Equations [50] and [51] are strictly valid only when adsorption is not significantly influenced by metal dissolution. An approach to include the effect of dissolution and, hence, potential on adsorption has been developed by Heusler and Cartledge<sup>109</sup> who proposed an additional process in which a metal atom from an uncovered area  $(1 - \sum \theta_j)$  reacts with an adsorbed ion from the covered area  $\theta_i$  to dissolve as ferrous ion. The adsorbed ion is then postulated to leave the surface during the reaction, thus contributing to the desorption process. Accordingly, eqn [49] is rewritten by adding an additional term, that is

$$v_{\text{des},i} = k_{\text{d},i}\theta_i \exp\left((1 - \beta) \sum_j A_{ij}\theta_j\right) + i_{\text{des},i} \quad [52]$$

where the desorption current  $i_{\text{des},i}$  is given by

$$i_{\text{des},i} = k_{\text{r},i}\theta_i \left(1 - \sum_j \theta_j\right) a_X \exp\left(\frac{\beta FE}{RT}\right) \quad [53]$$

where  $a_X$  is the activity of possible additional species (e.g.,  $\text{OH}^-$ ) that participate in the dissolution. In eqn [53], the desorption current is potential-dependent because it involves the dissolution of the metal. Equation [53] can be combined with eqns [48] and [52] to form a system of  $n$  equations for a solution with  $n$  adsorbable species. This system can be solved numerically for the coverage fractions  $\theta_i$  of each adsorbed species. Because of the potential dependence, the model predicts that the adsorption coverage rapidly decreases above a certain potential range.

It should be noted that a detailed treatment of adsorption is not always necessary for modeling aqueous corrosion. In particular, the potential dependence of adsorption can be often neglected. In most cases, simplified approaches are warranted. Specifically, for low surface coverage, the fraction  $\theta_i$  can be assumed to be proportional to the activity of the species  $i$  as shown by eqn [51]. Thus, eqns [43] and

[44] can often be simplified by using activities of species rather than their surface coverages.

### 2.38.3.3 Partial Electrochemical Reactions

The behavior of a corroding system results from the interplay of at least two and, frequently, many partial electrochemical reactions. Such reactions include:

1. anodic dissolution of pure metals and alloys in both the active and passive state;
2. reduction of protons, which is usually the primary cathodic reaction in acid corrosion;
3. reduction of water molecules, which is frequently the main cathodic reaction in deaerated neutral and alkaline solutions;
4. reduction of dissolved species that can act as proton donors such as undissociated carboxylic acids, carbonic acid, hydrogen sulfide, and numerous ions that contain protons (e.g., bicarbonates, bisulfides, etc.);
5. reduction of oxygen, which is a common cathodic process in aerated solutions;
6. reduction of metal ions at high oxidation states such as Fe(III) or Cu(II), which can be reduced to a lower oxidation state;
7. reduction of oxyanions such as nitrites, nitrates, or hypochlorites in which a nonmetallic element is reduced to a lower oxidation state;
8. oxidation of water to oxygen, which occurs at high potentials and, therefore, is rarely important in freely corroding systems; and
9. oxidation of metals to higher oxidation states, for example, Cr(III) to Cr(VI), which may occur in the transpassive dissolution region of stainless steels and nickel base alloys.

In this section, we present illustrative examples of how these reactions can be modeled in practice.

#### 2.38.3.3.1 Anodic reactions

The dissolution of several pure metals such as iron, copper, or nickel has been extensively investigated. Thus, it is possible to construct practical equations for the partial anodic dissolution processes on the basis of mechanistic information. For most alloys, detailed mechanistic information is not available and, therefore, it is necessary to establish kinetic expressions on a more empirical basis.

For iron dissolution, various multistep reaction mechanisms have been proposed. They have been reviewed in detail by Lorenz and Heusler,<sup>110</sup> Drazic,<sup>111</sup> and Keddam.<sup>112</sup> From the point of view of

modeling, particularly important parameters are the electrochemical transfer coefficient and reaction orders with respect to the ions that participate in anodic dissolution. Although there are substantial differences between the various proposed mechanisms, the dependence of the iron dissolution rate in acidic solutions on the activity of hydroxide ions is generally accepted. The mechanism proposed by Bockris *et al.*,<sup>113</sup> that is

predicts that the reaction order with respect to the  $\text{OH}^-$  ion is one because of the intermediate step of  $\text{OH}^-$  adsorption. The validity of this prediction has been verified for acidic solutions. Other mechanisms yield reaction orders between one and two. Additionally, the current density for iron dissolution has been found to depend on the activity of water (Smart and Bockris<sup>114</sup>). The mechanism of Bockris *et al.*<sup>113</sup> also predicts that the anodic transfer coefficient is  $\alpha_{\text{Fe}} = 1.5$ , which is consistent with experimentally observed Tafel slopes of 30–40 mV. Thus, the current density for Fe dissolution in acidic solutions can be expressed as

$$i_{\text{Fe,OH}} = i_{\text{Fe,OH}}^* a_{\text{OH}} a_{\text{H}_2\text{O}}^c \exp\left(\frac{\alpha_{\text{Fe}} F(E - E_{0,\text{Fe}})}{RT}\right) \quad [57]$$

where  $i_{\text{Fe,OH}}^*$  is a temperature-dependent coefficient, the subscript Fe,OH indicates that the dissolution reaction is mediated by  $\text{OH}^-$  ions, and  $c$  is an empirically determined reaction order with respect to the activity of water. According to Smart and Bockris<sup>114</sup>  $c = 1.6$ . The effect of the activity of water on the current density becomes significant for concentrated solutions, for which the activity of water is usually significantly lower than 1.

Although the reaction order with respect to the  $\text{OH}^-$  ions is valid for acidic solutions, it has been found that iron dissolution proceeds with little influence of pH for solutions with pH above  $\sim 4$ . Bockris *et al.*<sup>113</sup> explained this phenomenon by assuming a certain nonzero reaction order with respect to  $\text{Fe}^{2+}$  and by considering the hydrolysis of the  $\text{Fe}^{2+}$  ions that result from the dissolution. Alternatively, the change in the reaction order with respect to  $\text{OH}^-$  ions can be reproduced by assuming that the exchange current density is proportional to the surface coverage

by  $\text{OH}^-$  ions. This assumption is consistent with the reaction mechanism (see eqns [54]–[56]). Thus, eqn [57] can be generalized as<sup>108</sup>:

$$i_{\text{Fe,OH}} = i_{\text{Fe,OH}}^* \theta_{\text{OH}} a_{\text{H}_2\text{O}}^c \exp\left(\frac{\alpha_{\text{Fe}} F(E - E_{0,\text{Fe}})}{RT}\right) \quad [58]$$

Assuming that  $\theta_{\text{OH}}$  follows the Langmuir adsorption model, eqn [58] can be rewritten as

$$i_{\text{Fe,OH}} = i_{\text{Fe,OH}}^* \frac{a_{\text{OH}}}{1 + K_{\text{OH}} a_{\text{OH}}} a_{\text{H}_2\text{O}}^c \exp\left(\frac{\alpha_{\text{Fe}} F(E - E_{0,\text{Fe}})}{RT}\right) \quad [59]$$

Equation [59] reduces to eqn [57] for low activities of  $\text{OH}^-$ , that is, for acidic solutions. For higher concentrations of hydroxide ions, the reaction order with respect to  $\text{OH}^-$  becomes zero. This is consistent with the lack of a dependence of the Fe oxidation reaction on pH in  $\text{CO}_2$  corrosion of mild steel, which occurs at pH values above  $\sim 4$  (Nešić *et al.*,<sup>115</sup> Nordsveen *et al.*<sup>116</sup>).

The effect of halide ions on the dissolution of iron and carbon steel is of particular interest. Adsorbed halide ions may accelerate the anodic dissolution, especially in concentrated halide solutions. A number of reaction mechanisms have been proposed to explain this phenomenon. In particular, Chin and Nobe<sup>117</sup> and Kuo and Nobe<sup>118</sup> developed a mechanism that postulates a reaction route that is parallel to eqns [52]–[54]. An essentially identical mechanism has also been proposed by Drazic and Drazic.<sup>119</sup> According to this mechanism, a halide-containing surface complex is responsible for the dissolution. Thus, eqn [54] is followed by the following parallel route:

The mechanism eqns [60]–[62] results in a dissolution current density that depends on the activities of both halide and hydroxide ions. In acidic solutions, an equation analogous to eqn [57] can be written as

$$i_{\text{Fe,X}} = i_{\text{Fe,X}}^* a_{\text{X}^-}^s a_{\text{OH}^-}^t \exp\left(\frac{\alpha_{\text{Fe}} F(E - E_{0,\text{Fe}})}{RT}\right) \quad [63]$$

where the subscript X indicates the halide ions that mediate the reaction. For chloride systems,  $s = 0.4$  and  $t = 0.6$  when concentrations are used instead of

activities.<sup>118</sup> Since the mechanism described by eqns [60]–[62] is assumed to be parallel to the mechanism under halide-free conditions, the total current density of anodic dissolution can be assumed to be a sum of the contributions of two mechanisms. Also, eqn [63] can be generalized to neutral solutions in analogy with eqn [59]. Additionally, the desorption current density (eqn [53]) contributes to the total current, although it becomes important only at relatively high potentials, and its numerical significance is usually limited. Thus, the expression for the total active Fe dissolution current in halide solutions becomes<sup>108</sup>

$$i_{\text{Fe}} = i_{\text{Fe,OH}} + i_{\text{Fe,X}} + i_{\text{des,i}} \quad [64]$$

As with iron, anodic dissolution of copper has also been extensively investigated. Kear *et al.*<sup>120</sup> reviewed the mechanisms and associated expressions for the current density of anodic dissolution of copper in the active state in chloride environments. Copper dissolution is generally thought to proceed through the formation of cuprous chloride complexes and to be under mixed, charge-transfer and transport, control close to the corrosion potential. Several authors (Lee and Nobe,<sup>121</sup> Deslouis *et al.*,<sup>122</sup> King *et al.*<sup>123</sup>) assumed the following mechanism:

The expression for the anodic current density derived from eqns [65] and [66] is

$$\frac{i_{\text{Cu}}}{nF} = \frac{k_1 k_2}{k_{-1}} a_{\text{Cl}}^2 \exp\left(\frac{F(E - E_{0,\text{Cu}})}{RT}\right) - k_{-2} a_{\text{CuCl}_2^-} \quad [67]$$

Since the reaction rate depends on the activity of the reaction products ( $\text{CuCl}_2^-$ ) at the surface (see the second term on the right-hand side of eqn [67]), the reaction is partially controlled by the mass transport of the  $\text{CuCl}_2^-$  ions, and the anodic current density is simultaneously equal to

$$\frac{i_{\text{Cu}}}{nF} = D_{\text{CuCl}_2^-} \frac{a_{\text{CuCl}_2^-}}{\delta_{\text{CuCl}_2^-}} \quad [68]$$

Equation [68] is a special case of eqn [39] when the bulk concentration of  $\text{CuCl}_2^-$  is negligible.

Much less mechanistic information is available for the anodic dissolution of alloys in the active state. In the case of stainless steels and nickel-base alloys, this is due to the fact that dissolution of these metals in

the passive state is more important than in the active state. For these alloys, active dissolution is of importance only in acidic solutions. In this case, expressions for anodic dissolution need to be established on an empirical basis. For stainless steels and nickel-base alloys, a positive reaction order between one and two with respect to hydroxide ions is observed. While such values are similar to those observed for Fe, the exchange current densities are very different and need to be determined separately for individual alloys.

### 2.38.3.3.2 Cathodic reactions

Among the numerous possible partial cathodic processes, the reduction of protons, water molecules, and dissolved oxygen is ubiquitous in aqueous corrosion. Reduction of protons is an important cathodic process in acidic solutions. The overall reaction is given by

The mechanisms of this reaction have been reviewed by Vetter<sup>98</sup> and Kaesche.<sup>100</sup> Proton reduction proceeds in two steps according to two alternative mechanisms. The Volmer–Heyrovsky mechanism applies to most metals, whereas the Volmer–Tafel mechanism may be observed on certain noble metals. The Volmer–Heyrovsky mechanism can be represented as a sequence of two elementary reactions, that is

It is generally accepted that the  $\text{H}^+$  reduction reaction may proceed under activation or mass transfer control. The cathodic process of  $\text{H}^+$  reduction can be modeled assuming that the reaction order with respect to the protons is equal to one. Then, eqns [41] and [42] can be directly used for modeling. In addition to its dependence on the activity of protons, there is empirical evidence that the  $\text{H}^+$  reduction depends on the activity of water. According to Smart *et al.*,<sup>124</sup> the reaction order with respect to water activity is 2.2 on iron. The electrochemical transfer coefficient can be assumed to be equal to  $\sim 0.5$  for carbon steels and many corrosion-resistant alloys, which corresponds to a Tafel slope of 118 mV at 25 °C.

As the pH of a solution increases, the importance of the proton reduction reaction rapidly decreases. In neutral and alkaline solutions, the reduction of water molecules becomes predominant unless stronger oxidizing agents (e.g., oxygen) are present in the system. The water reduction is given by

and is thermodynamically equivalent to the reduction of protons. However, its kinetic characteristics are different. Unlike the reduction of protons, the water reduction reaction typically does not exhibit a limiting current density because there are no diffusion limitations for the transport of  $\text{H}_2\text{O}$  molecules to the surface. This remains true as long as the system is predominantly aqueous. The water reduction process can be modeled by assuming the same reaction order with respect to  $\text{H}_2\text{O}$  as that for proton reduction. Also, practically the same value of the electrochemical transfer coefficient can be assumed.

Reduction of oxygen, that is

is the predominant cathodic reaction in aerated aqueous solutions unless the solution contains stronger oxidizing agents such as ferric, cupric, or hypochlorite ions. The mechanism of oxygen reduction is substantially more complex than the mechanisms of  $\text{H}^+$  or  $\text{H}_2\text{O}$  reduction. Oxygen reduction on iron and carbon steel has been reviewed by Jovancicevic and Bockris,<sup>125</sup> Zecevic *et al.*,<sup>126</sup> and Jovancicevic.<sup>127</sup> On stainless steels, it has been analyzed by Le Bozec *et al.*,<sup>128</sup> Kapusta,<sup>129</sup> and in papers cited therein. On copper, it has been studied by King *et al.*<sup>130</sup> In general, it has been established that the reaction may proceed either through a four-electron pathway, which leads to the reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}$ , or through a two-electron pathway, which leads to the formation of  $\text{H}_2\text{O}_2$  as an intermediate. An overall reaction scheme may be represented as

where the subscripts 'surf' and 'ads' denote the oxygen in the diffusion layer close to the surface and oxygen adsorbed on the surface, respectively. The absorbed intermediate  $\text{H}_2\text{O}_2$  can be either further reduced to  $\text{OH}^-$  or desorbed and dissolved in the solution or converted back to oxygen through decomposition or reoxidation. The actual reaction pathway is influenced by many factors such as the surface treatment of the electrode.<sup>128</sup> However, the four-electron reduction path from  $\text{O}_2$  to  $\text{OH}^-$  seems to predominate.<sup>129</sup> Oxygen reduction may be under charge transfer or mass transfer control, due to the diffusion of dissolved oxygen molecules. For passive metals, the process is usually under charge transfer control because the limiting

current density for oxygen reduction is usually greater than the passive current density at typical dissolved oxygen concentrations.

For modeling purposes, the key parameters are the electrochemical transfer coefficient and the reaction orders with respect to dissolved oxygen and protons. These parameters determine the dependence of the reduction reaction on dissolved oxygen concentration (or, equivalently, the partial pressure of oxygen) and on pH. Once these parameters are known, the oxygen reduction process can be modeled on a semi-empirical basis. The current density for oxygen reduction can be written as:

$$i_{\text{O}_2} = i_{\text{O}_2}^* a_{\text{O}_2,s}^q a_{\text{H}^+,s}^r \exp \left[ \frac{-\alpha_{\text{O}_2} F (E - E_{0,\text{O}_2})}{RT} \right] \quad [75]$$

Equation [75] needs to be coupled with eqn [37] with  $n=4$  for mass-transfer limitations. The reaction orders  $q$  and  $r$  in eqn [75] are, in general, specific to the metal surface although they are expected to be similar within families of alloys. For stainless steels, there seems to be a consensus that the reaction order with respect to dissolved oxygen is 0.5 (Kapusta,<sup>129</sup> Sridhar *et al.*<sup>131</sup>), whereas the order with respect to protons ranges from 0.5 to 1 (or, equivalently, the order with respect to hydroxide ions varies from  $-0.5$  to  $-1$ ). For passive iron or carbon steel, the reaction order with respect to  $\text{O}_2$  has been reported as 0.5 (Calvo and Schiffrin<sup>132</sup>) or 1 (Jovancicevic and Bockris,<sup>125</sup> Jovancicevic<sup>127</sup>). For copper, a value of 1 has been reported (King *et al.*<sup>130</sup>).

Another important cathodic reaction is the reduction of transition metal ions such as  $\text{Fe}^{3+}$  and  $\text{Cu}^{2+}$  to lower oxidation states, for example

This process can be modeled as a first-order reaction with respect to the activity of ferric ions by taking into account the mass transport limitations (eqn [37]).

All the cathodic reactions discussed above may proceed under mass transfer limitations due to the diffusion of reactants to the corroding surface. However, cathodic limiting current densities may also arise because of limitations due to homogeneous reactions in the solution. A prominent example of such a reaction is the reduction of carbonic acid, which is the key cathodic process in  $\text{CO}_2$  corrosion of carbon steel. This reaction accounts for the substantially higher corrosivity of  $\text{CO}_2$  solutions than mineral acid solutions at the same pH. Carbonic acid results from the hydration of dissolved  $\text{CO}_2$ , that is

Reaction eqn [77] is followed by the reduction of  $\text{H}_2\text{CO}_3$  on the surface, that is

which is thermodynamically equivalent to the reduction of protons, but is characterized by different kinetics. The  $\text{H}_2\text{CO}_3$  reduction is under activation or chemical reaction control, and can be modeled using eqn [41]. The charge transfer current is expressed as (Nešić *et al.*<sup>115</sup>):

$$i_{\text{H}_2\text{CO}_3} = i_{\text{H}_2\text{CO}_3}^* a_{\text{H}_2\text{CO}_3} a_{\text{H}^+}^{-0.5} \exp \left[ \frac{-\alpha_{\text{H}_2\text{CO}_3} F (E - E_{0,\text{H}})}{RT} \right] \quad [79]$$

where the transfer coefficient can be assumed to be equal to that for  $\text{H}_2\text{O}$  reduction. The limiting current density can be calculated from an equation developed by Nešić *et al.*<sup>115</sup> on the basis of a formula derived by Vetter<sup>98</sup> for processes with a rate-determining homogeneous reaction in the solution. Here, the rate-determining reaction is the hydration of  $\text{CO}_2$  and the limiting current density is:

$$i_{\text{H}_2\text{CO}_3,\text{L}} = F a_{\text{H}_2\text{CO}_3} \left( D_{\text{H}_2\text{CO}_3} K_{\text{H}_2\text{CO}_3} k_{\text{H}_2\text{CO}_3}^f \right)^{1/2} \quad [80]$$

where  $D_{\text{H}_2\text{CO}_3}$ ,  $K_{\text{H}_2\text{CO}_3}$ , and  $k_{\text{H}_2\text{CO}_3}^f$  are the diffusion coefficient of  $\text{H}_2\text{CO}_3$ , equilibrium constant for the hydration of  $\text{CO}_2$ , and forward reaction constant for the hydration reaction, respectively.

### 2.38.3.3.3 Temperature dependence

The rates of the majority of partial anodic and cathodic processes are strongly dependent on temperature. This temperature dependence can be modeled by assuming that the concentration-independent part of the exchange current density (here denoted by  $i^*$ ) is expressed as

$$i^*(T) = i^*(T_{\text{ref}}) \exp \left[ -\frac{\Delta H^\ddagger}{R} \left( \frac{1}{T} - \frac{1}{T_{\text{ref}}} \right) \right] \quad [81]$$

Equation [81] is equivalent to assuming a constant enthalpy of activation  $\Delta H^\ddagger$  for each partial process.

### 2.38.3.4 Modeling Mass Transport Using Mass Transfer Coefficients

To calculate the mass-transport effects on electrochemical kinetics according to eqns [37]–[40], it is necessary to predict the diffusion layer thickness  $\delta_i$

or, equivalently, the limiting current density. Theoretical formulas for these quantities cannot be obtained for arbitrary flow conditions and, therefore, empirical approaches are necessary for most practical applications.

In the case of a rotating disk electrode, a theoretical solution has been derived by Levich.<sup>133</sup> It is noteworthy that Levich's solution preceded experimental results. The thickness of the diffusion layer on a rotating disk electrode is

$$\delta_i = 1.61 D_i^{1/3} \nu^{1/6} \omega^{-1/2} \quad [82]$$

where  $D_i$  is the diffusion coefficient of the reacting species,  $\omega$  is the rotation rate, and  $\nu$  is the kinematic viscosity, which is the ratio of the dynamic viscosity and density, that is

$$\nu = \eta / \rho \quad [83]$$

In view of the relationships between the thickness of the diffusion layer and the limiting current density (eqns [38] and [40]), a physically equivalent predictive expression can be written for the limiting current density. For example, the limiting current density of a cathodic reaction (eqn [38]) then becomes:

$$i_{\text{c,L}} = -0.6205 n F c_{0,\text{b}} D_o^{2/3} \nu^{-1/6} \omega^{1/2} \quad [84]$$

For many other flow geometries, mass transport can be calculated using empirical correlations expressed in terms of the mass transfer coefficient  $k_m$ . In general, the mass transfer coefficient is defined as

$$k_m = \frac{\text{Reaction rate}}{\text{Concentration driving force}} \quad [85]$$

For an electrochemical reaction, the reaction rate is expressed using the current density, and eqn [36] for a mass transport-limited reaction can be rewritten in terms of the mass transfer coefficient  $k_m$  as

$$\mathcal{J}_i = \frac{i_i}{n_i F} = -D_i \frac{c_{i,\text{b}} - c_{i,\text{s}}}{\delta_i} = -k_{m,i} (c_{i,\text{b}} - c_{i,\text{s}}) \quad [86]$$

This indicates a relationship between  $\delta_i$  and  $k_{m,i}$  that is

$$k_{m,i} = \frac{D_i}{\delta_i} \quad [87]$$

Mass transport rates can be expressed using dimensionless groups, for which empirical correlations can be developed for a number of flow patterns. The mass transfer coefficient  $k_m$  enters into the Sherwood number  $Sh$ , which is defined as

$$Sh = \frac{k_m d}{D} \quad [88]$$

where  $d$  is a characteristic dimension (e.g., a pipe or rotating disk diameter);  $D$ , a diffusion coefficient; and the subscript  $i$  has been dropped for convenience as it is understood that eqn [88] is written for individual reacting species. The Sherwood number can be correlated with the Reynolds ( $Re$ ) and Schmidt ( $Sc$ ) numbers, which are defined as

$$Re = \frac{Vd}{\nu} \quad [89]$$

$$Sc = \frac{\nu}{D} \quad [90]$$

where  $V$  is the linear velocity. It can be shown by dimensional analysis that  $Sb$  is a function of  $Re$  and  $Sc$ . This function typically has the form<sup>134,135</sup>

$$Sb = \text{Const} \times Re^x \times Sc^y \quad [91]$$

where  $x$  is usually between 0.3 and 1 and  $y$  is about 1/3. For example, the theoretically derived results for the rotating disk can be recast in terms of the mass transfer coefficient as

$$Sb = 0.6205 Re^{0.5} Sc^{0.33} \quad [92]$$

Empirical expressions for other flow geometries have been reviewed by Poulson<sup>134,135</sup> for single-phase flow conditions. Equations of the type eqn [91] exist for the rotating cylinder, impinging jet, nozzle or orifice, and pipe flow. For the rotating cylinder, the correlation of Eisenberg *et al.*<sup>136</sup> is widely used

$$Sb = 0.0791 Re^{0.70} Sc^{0.356} \quad [93]$$

For single-phase flow in a straight pipe, several correlations have been developed. Among these equations, Berger and Hau<sup>137</sup> correlation has found use in a number of corrosion modeling studies:

$$Sb = 0.0165 Re^{0.86} Sc^{0.33} \quad [94]$$

The earlier pipe flow formulas have been reviewed by Poulson,<sup>134</sup> and the use of more recent equations has been discussed by Lin *et al.*<sup>138</sup> Equations of this kind are not as well developed for multiphase flow. Correlations are available for stratified flow (Wang and Nešić<sup>139</sup>), but a comprehensive treatment is not available for various regimes of multiphase flow. Therefore, a convenient alternative is to base the computation of mass transfer coefficients on the well-known analogy between heat and mass transfer.

The analogies between the transport of mass, momentum, and heat can be understood by considering the similarity between their respective mathematical formulations, namely, Fick's law of diffusion, Newton's law of viscosity, and Fourier's law of heat conduction.

Thus, once a relationship has been established for a given phenomenon in terms of dimensionless numbers, it can further serve for the calculation of another phenomenon that takes place under the same geometric and physical conditions but with different velocities, dimensions, and physical properties of the system. In particular, the correlations established for heat transfer can be used for mass transfer calculations. The analogy between the heat, mass, and momentum transfer has been stated in a dimensionless form by Chilton and Colburn<sup>140</sup> as

$$\frac{Sb}{Re Sc^{1/3}} = \frac{Nu}{Re Pr^{1/3}} = \frac{f}{2} \quad [95]$$

where the Nusselt number,  $Nu$ , and the Prandtl number,  $Pr$ , are the heat transfer equivalents of the Sherwood and Schmidt numbers in mass transfer, respectively, and  $f$  is a friction factor. Correlations for the friction factor are available as a function of pipe roughness, its diameter, and the Reynolds number (Frank<sup>141</sup>). The exponent 1/3 in eqn [95] can be replaced with a generalized exponent  $n$ . The Nusselt and Prandtl numbers are defined as

$$Nu = \frac{bd}{\lambda} \quad [96]$$

$$Pr = \frac{\nu}{\alpha} \quad [97]$$

where  $b$  is the convection heat transfer coefficient;  $\lambda$ , the thermal conductivity; and  $\alpha$ , the thermal diffusivity ( $\alpha = \lambda/\rho C_p$ ).

This relationship makes it possible to determine the mass transfer coefficient in two-phase flow systems for which experimental heat transfer correlations are available. Heat transfer correlations take the form

$$Nu = \text{Const} \times Re^x Pr^y \quad [98]$$

They have been reviewed by Kim *et al.*<sup>142</sup> and Adsani *et al.*<sup>143,144</sup> for annular, slug, and bubbly flow in horizontal and vertical tubes. Also, Adsani *et al.*<sup>143,144</sup> developed a correlation for calculating the two-phase Nusselt number, which is a generalization of the Chilton-Colburn<sup>140</sup> heat transfer expression (i.e., the second equality of eqn [95]):

$$Nu_{\text{two-phase}} = C_1 f_L^{C_2} \left( \frac{V_L d}{\nu} \right)^{C_3} Pr_L^{1/3} \quad [99]$$

where the liquid-phase friction factor  $f_L$  and velocity  $V_L$  are calculated using flow models for annular, slug, and bubbly flow, and  $C_1$ ,  $C_2$ , and  $C_3$  are fitting constants. Subsequently, the Sherwood number and the

mass transfer coefficient can be obtained from the first equality in eqn [95].

As shown in the above equations, the computation of the mass transfer coefficient requires the diffusion coefficients, viscosity, and density. Density is a thermodynamic property and, as such, can be calculated from any comprehensive thermodynamic model for electrolyte systems. For example, Wang *et al.*<sup>54</sup> describe how to calculate densities in a way that is consistent with other thermodynamic properties. The computation of viscosities and diffusion coefficients requires separate models, which are beyond the scope of this chapter. Viscosity and diffusivity models have been reviewed and critically evaluated by Corti *et al.*<sup>145</sup> with particular emphasis on systems at elevated temperatures.

### 2.38.3.4.1 Example of electrochemical modeling of general corrosion

To illustrate the application of the principles described earlier, Figure 5 shows the computation of the corrosion rate and potential of type 316 stainless steel in aqueous solutions of HF. These calculations have been made using the model of Anderko *et al.*<sup>108,146</sup> as implemented in the Corrosion Analyzer software.<sup>61</sup> The upper diagram shows the partial cathodic and anodic processes in a 2 m HF solution. Three cathodic processes are taken into account in this system: reduction of protons ( $H^+$ ), reduction of undissociated HF molecules, and reduction of water molecules. These partial processes are marked in Figure 5(a) as (1), (2), and (3), respectively. The  $H^+$  reduction reaction is modeled using eqns [41] and [42] as described earlier. The HF reduction process is calculated using the same equations, but with a different exchange current density. Both the  $H^+$  and HF reduction processes show partial current densities because of mass transport limitations for the transport of  $H^+$  and HF to the surface. Because of the low degree of dissociation of HF, the reduction of HF (line two in Figure 5(a)) plays a much more important role than the reduction of  $H^+$  ions (line 1). The partial anodic curve for the oxidation of 316 SS is labeled as (4). It is assumed that the alloy components dissolve congruently, and the dependence of the partial anodic current density on the acidity of the solution is analogous to that observed for Fe (see eqn [59]), but with a different exchange current density. The superposition of the partial cathodic and anodic processes yields a predicted polarization curve, which is shown by a thick line in Figure 5(a). The location of the mixed potential is calculated

according to eqn [45] with  $A_a = A_c$  and marked with a triangle. The complete model reproduces the experimental corrosion rates (Figure 5(b)) and corrosion potentials (Figure 5(c)) as a function of HF concentration and temperature.

### 2.38.3.5 Detailed Modeling of Mass Transport

The treatment of mass transport by the use of mass transfer coefficients is computationally efficient and is capable of reproducing steady-state corrosion behavior with good accuracy. However, it is subject to some limitations including:

1. it is suitable for calculating only steady-state behavior and, therefore, it is not appropriate for modeling time-dependent corrosion,
2. it neglects migration which introduces errors especially for dilute systems without a background electrolyte, and
3. it is not convenient for modeling transport in systems with geometrical constraints, especially when the cathodic and anodic areas are spatially separated; thus, it is not well suited for modeling the propagation of localized corrosion.

These limitations can be eliminated by a more comprehensive (but much more computationally demanding) treatment of transport phenomena. This treatment is based on the conservation laws for each species in the solution (Newman<sup>150</sup>):

$$\frac{\partial c_k}{\partial t} = -\nabla \mathcal{J}_k + R_k \quad k = 1, \dots, K \quad [100]$$

where  $C_k$  is the concentration of species  $k$ ,  $t$  is the time,  $\mathcal{J}_k$  is the flux of species  $k$ ,  $\nabla$  is the vector differential operator (which reduces to  $\partial/\partial x$  in a one-dimensional case), and  $R_k$  is the rate of production (source) or depletion (sink) of this species as a result of chemical reactions. In the vast majority of practical applications, the dilute solution theory is used to calculate the flux of the species, that is

$$\mathcal{J}_k = -D_k \nabla c_k - z_k F u_k c_k \nabla \varphi + c_k v \quad [101]$$

where  $u_k$  is the mobility of species  $k$ ,  $\varphi$  is the electrostatic potential in the solution,  $v$  is the fluid velocity, and the other symbols were defined previously. In eqn [101], the first term on the right-hand side represents the contributions of diffusion, the second term describes migration, and the third term is a contribution of convection. In the migration term, the mobility can be calculated from the diffusivity using the Nernst–Einstein equation:

**Figure 5** Application of an electrochemical model of general corrosion<sup>108,146</sup> to type 316L stainless steel in aqueous HF solutions. The upper diagram (a) shows the partial cathodic and anodic processes in a 2 m HF solution. The middle (b) and lower (c) diagrams compare the calculated and experimental<sup>147–149</sup> corrosion rates and potentials, respectively.

$$u_k = \frac{D_k}{RT} \quad [102]$$

which is exact for species at infinite dilution and provides a good approximation at finite concentrations. An additional condition for determining the potential in eqn [101] is given by the Poisson equation:

$$\nabla^2 \varphi = -\frac{F}{\varepsilon} \sum_k z_k c_k \quad [103]$$

where  $\varepsilon$  is the dielectric permittivity of the solution. It can be shown<sup>150</sup> that, due to the large value of the ratio  $F/\varepsilon$ , even a very small separation of charges (i.e.,  $\sum z_k c_k \neq 0$ ) results in a large potential gradient,

which in turn prevents any appreciable separation of charge. Therefore, eqn [103] is very often replaced in practice by the simple electroneutrality condition, that is

$$\sum z_k c_k = 0 \quad [104]$$

which is one of the basic equations for computing equilibrium properties of electrolytes.

It should be noted that eqn [101] is rigorous only for dilute solutions. For concentrated solutions, its more general counterpart is<sup>150</sup>

$$\mathcal{F}_k = c_k v_k \quad [105]$$

where the velocities  $v_k$  of species  $k$  are determined by the multicomponent diffusion equations:

$$c_k \nabla \mu_k = RT \sum_j \frac{c_k c_j}{c_{\text{tot}} D_{kj}} (v_j - v_k) \quad [106]$$

where  $D_{kj}$  are the mutual diffusion coefficients, and  $c_{\text{tot}}$  is the total concentration of all components. The application of eqns [105] and [106] is very difficult due to the lack of a general methodology for computing  $D_{kj}$  and computational complexity. Therefore, eqns [105] and [106] have found few applications in practical models. However, a practical simplified form can be obtained for moderately dilute solutions for which the concentrations of solute species are smaller than the concentration of the solvent. Then, eqns [105] and [106] simplify to

$$\mathcal{F}_k = -\frac{D_k}{RT} c_k \nabla \mu_k + c_k v \quad [107]$$

Considering that  $\mu_k = \mu_k^0 + RT \ln c_k \gamma_k + z_k F \varphi$ , the flux equation becomes<sup>150</sup>

$$\mathcal{F}_k = -D_k \nabla c_k - z_k F u_k c_k \nabla \varphi + c_k v - D_k c_k \nabla \ln \gamma_k \quad [108]$$

which is only moderately more complex than the dilute-solution eqn [101], but benefits from the information on solution nonideality that is embedded in the activity coefficient and can be calculated from an electrolyte thermodynamic model.

In the convective term of eqn [101] or [108], the instantaneous fluid velocity ( $v$ ) can be calculated, in principle, by the methods of computational fluid dynamics. However, such calculations involve a large computational effort and are, in practice, limited with respect to flow geometries and conditions. For turbulent flow, a practical approach relies on introducing turbulent diffusion. Accordingly, instantaneous velocity is divided into steady and turbulent components. The steady component is parallel to the surface and does not contribute to transport to and from the surface. Then, the convection term in eqn [101] or [108],

$c_k v$ , is approximated by a turbulent diffusivity term,  $-D_t \nabla c_k$ , which can be lumped with the molecular diffusion term thus defining an effective diffusion coefficient (Davis,<sup>151</sup> Nordsveen *et al.*<sup>116</sup>)

$$D_k^{\text{eff}} = D_k + D_t \quad [109]$$

where  $D_t$  can be obtained from empirical correlations with fluid properties.<sup>151,152</sup> For example, Davis's<sup>151</sup> correlation has been used in the CO<sub>2</sub> corrosion model of Nordsveen *et al.*<sup>116</sup>:

$$D_t = 0.18 \left( \frac{z}{\delta} \right)^3 \frac{\eta}{\rho} \quad [110]$$

where  $z$  represents the distance from the surface (either a metal surface or a surface covered with corrosion products),  $\eta$  is the viscosity,  $\rho$  is the density, and  $\delta$  is the thickness of the laminar boundary layer, which can be calculated for a pipe with a diameter  $d$  as

$$\delta = 25 Re^{-7/8} d \quad [111]$$

It is noteworthy that this formalism can be shown to be physically equivalent to the treatment of turbulent flow through mass transfer coefficients as described in the previous section. Specifically, Wang and Nešić<sup>139</sup> showed a relationship between the mass transfer coefficient and  $D_t$ :

$$\frac{1}{k_{m,i}} = \int_0^\delta \frac{dz}{D_i + D_t} \quad [112]$$

The computation of the rates of production or depletion  $R_k$  is necessary in order to apply eqn [100]. A general matrix formalism for calculating the  $R_k$  terms in a system with multiple reactions has been developed by Nordsveen *et al.*<sup>116</sup> The main limitation here is the fact that rate data are available only for a very limited number of reactions such as precipitation of common scales (CaCO<sub>3</sub>, FeCO<sub>3</sub>) and selected homogeneous reactions (e.g., hydration of H<sub>2</sub>CO<sub>3</sub>). For the vast majority of reactions, only equilibrium equations are available and, in fact, there is no physical need for kinetic expressions for most homogeneous reactions because they are fast relative to mass transport. Therefore, arbitrary rate expressions may be assumed as long as they are constrained by the equilibrium constant (i.e., the ratio of the forward and reverse rate constants is equal to the equilibrium constant), give appropriately fast reaction rates and change direction as the equilibrium point is crossed. A convenient expression for the production or depletion rate for species  $k$  can be defined in terms of the departure of the ionic product from equilibrium (Walton<sup>153</sup>):

$$R_k = \sum_{m=1}^M \left[ -r_m v_{km} \ln \left( \frac{\prod c_k^{v_{km}}}{K_m} \right) \right] \quad [113]$$

where  $r_m$  is an adjustable numerical rate parameter for reaction  $m$ ,  $K_m$  is the equilibrium constant for reaction  $m$ , and  $v_{km}$  is the stoichiometric coefficient for species  $k$  in the  $m$ th reaction. Alternatively, the transport equations can be first solved separately from the chemical effects and, then, at the end of each sufficiently small time step, thermodynamic equilibrium calculations can be performed in each elementary volume.

To solve the system of transport eqns [100] and [101] or [108], boundary conditions are required. In the bulk solution, the equilibrium concentrations are the natural boundary conditions. For each species involved in electrochemical reactions, the flux at the metal surface is determined from

$$\mathcal{J}_k = -\frac{i_k}{n_k F} \quad [114]$$

where the current density  $i_k$  is calculated from appropriate expressions for cathodic and anodic partial processes as a function of concentrations at the metal surface. This provides a link to the mechanistic or empirical electrochemical expressions described above. For the species that are not involved in the reactions, the flux at the interface is zero. It should be noted that the application of this formalism of mass transport can become quite computationally involved, especially for systems with numerous species, because it requires solving a system of differential equations (eqns [100] and [101] or [108]) with constraints (eqns [103] or [104] and chemical terms).

### 2.38.3.5.1 Effect of the presence of porous media

The above transport equations need to be modified when mass transport occurs through porous media such as corrosion products, calcareous deposits, soil or sand, and various man-made environments, including concrete and ceramics. Such a generalization can be formulated in terms of two characteristic quantities, porosity and tortuosity. Porosity ( $\varepsilon$ ) is the volumetric void fraction of the medium, whereas tortuosity ( $\tau$ ) is defined as the ratio of the distance that an ion or molecule travels around solid particles to the direct path. For practical applications, tortuosity can be correlated with porosity thus leaving porosity as the only parameter to affect transport equations. The generalization of transport equations to porous media has been

discussed by Newman<sup>150</sup> and Bear.<sup>154</sup> A detailed corrosion model that includes the transport in porous corrosion products has been developed for CO<sub>2</sub> corrosion by Nordsveen *et al.*<sup>116</sup> and Nešić and Lee.<sup>155</sup>

### 2.38.3.6 Active–Passive Transition and Dissolution in the Passive State

The expressions for anodic partial current densities discussed above (eqns [54]–[68]) are limited to the dissolution in the active state. However, dissolution in the passive state and the transition between the active and passive state are equally important for modeling aqueous corrosion. In fact, passivity is the key to our metal-based civilization (Macdonald<sup>97</sup>) and has been extensively investigated since the pioneering work of Faraday and Schönbein in the 1830s. Theories of passivity have been reviewed by many investigators (Frankenthal and Kruger,<sup>156</sup> Froment,<sup>157</sup> Marcus and Oudar,<sup>158</sup> Natishan *et al.*,<sup>159</sup> Macdonald<sup>97,160</sup>) and are beyond the scope of this chapter. In this section, we focus solely on practical models for calculating the anodic current density in the passive and active–passive transition regions as a function of solution chemistry.

Passivity manifests itself by a sharp drop in the anodic current density at a certain critical potential as the metal is polarized in a negative-to-positive potential direction. For calculation purposes, empirically determined anodic polarization curves can be reproduced using a suitable fitting function. For example, such a function has been developed by Macdonald.<sup>161</sup> Then, empirical fitting functions can be used within the framework of the mixed potential theory as described above.

A convenient way to introduce the active–passive transition into a computational model is to consider a current that leads to the formation of a passive layer in addition to the current that leads to active dissolution (Ebersbach *et al.*,<sup>162</sup> Anderko and Young<sup>108</sup>). For this purpose, a certain fraction of the surface  $\theta_p$  can be assumed to be covered by a passive layer. The change of the passive layer coverage fraction with time can be expressed as

$$\left( \frac{\partial \theta_p}{\partial t} \right)_{E, a_i} = c i_{\text{MeO}} (1 - \theta_p) - K \theta_p \quad [115]$$

where  $i_{\text{MeO}}$  is the current density that contributes to the formation of a passive layer. The second term on the right-hand side of eqn [115] represents the rate of dissolution of the passive layer, which is

proportional to the coverage fraction. Solution of this equation in the steady-state limit yields an expression for the anodic dissolution current:

$$i_{\text{Me,TOT}} = \frac{i_{\text{Me}} + i_{\text{MeO}}}{1 + (i_{\text{MeO}}/K)} = \frac{i_{\text{Me}} + i_{\text{MeO}}}{1 + (i_{\text{MeO}}/i_{\text{p}})} \quad [116]$$

where  $i_{\text{Me}}$  is the dissolution current density in the active state and the ratio  $i_{\text{p}} = c/K$  constitutes the passive current density. The current  $i_{\text{Me}}$  is calculated using the active dissolution models described above. The current  $i_{\text{MeO}}$  is expressed using the usual expression for process under activation control, that is

$$i_2 = i_2^0 \exp\left(\frac{\alpha_2 F(E - E_{\text{F}})}{RT}\right) \quad [117]$$

in which the parameters can be adjusted to reproduce the observable characteristics of the active-passive transition including the critical current density ( $i_{\text{crit}}$ ) and Flade potential ( $E_{\text{F}}$ ).<sup>146</sup> Equation [116] can be then used for the anodic process of metal dissolution within the framework of the mixed-potential theory (eqns [45] and [46]).

An example of mixed-potential calculations for a passive metal is shown in **Figure 6**. This figure illustrates the computation of the corrosion potential of alloy 600 in a dilute LiOH solution as a function of dissolved oxygen concentration. As in **Figure 5**, the upper and middle diagrams of **Figure 6** show the predicted partial  $E$  versus  $i$  curves for the anodic and cathodic processes. The upper diagram (**Figure 6(a)**) shows the predictions for a very low  $\text{O}_2$  concentration (0.013 ppm), whereas the concentration in the middle diagram is somewhat higher (0.096 ppm). In a weakly alkaline solution, the alloy is passive as indicated by the vertical portion of the anodic curve (line labeled as (3)). Two main cathodic processes are taken into account in this system, that is, the reduction of  $\text{H}_2\text{O}$  (line (1)) and the reduction of  $\text{O}_2$  (line (2)). At the lower  $\text{O}_2$  concentration, the limiting current density is lower than the passive current density, and the main cathodic process is the reduction of  $\text{H}_2\text{O}$  (i.e., the mixed potential lies at the intersection of the lines (1) and (3) in **Figure 6(a)**). As the  $\text{O}_2$  concentration increases, the  $\text{O}_2$  reduction reaction becomes predominant and determines the mixed potential, which then lies at the intersection of lines (2) and (3). This behavior explains the experimentally determined s-shaped dependence of  $E_{\text{corr}}$  on  $\text{O}_2$  concentration as shown in **Figure 6(c)**. The s-shape is due to the transition from  $\text{H}_2\text{O}$  reduction to  $\text{O}_2$  reduction as the dominant cathodic process. The transition

depends on flow conditions because the  $\text{O}_2$  reduction is partially under mass transport control.

Passive dissolution and active-passive transition strongly depend on solution chemistry. In the absence of specific active ions, the dissolution of oxide films depends primarily on the pH of the solution. Appropriate kinetic expressions can be constructed by considering dissolution reactions between the passive oxide/hydroxide surface layers and solution species (Anderko *et al.*,<sup>146</sup> Sridhar *et al.*<sup>131,164</sup>) In acidic solutions, the key reaction involves the protons from the solution:

where the symbol ‘ $\equiv$ ’ denotes surface species. The corresponding kinetic equation is

$$i_{\text{p,H}^+} = k_{\text{H}^+} a_{\text{H}^+,s}^q \quad [119]$$

where  $a_{\text{H}^+,s}$  denotes the surface concentration of hydrogen ions and  $q$  is a reaction order, which is not necessarily related to the stoichiometric coefficient in the dissolution reaction. In neutral solutions, the predominant dissolution reaction can be written as

where the predominant species on the right-hand side of eqn [120] is a neutral complex as indicated by the superscript 0. The corresponding kinetic equation is

$$i_{\text{p,H}_2\text{O}} = k_{\text{H}_2\text{O}} a_{\text{H}_2\text{O},s}^r \quad [121]$$

where the reaction order with respect to water indicates that dissolution may be affected by water activity. Similarly, the predominant reaction in alkaline solutions is

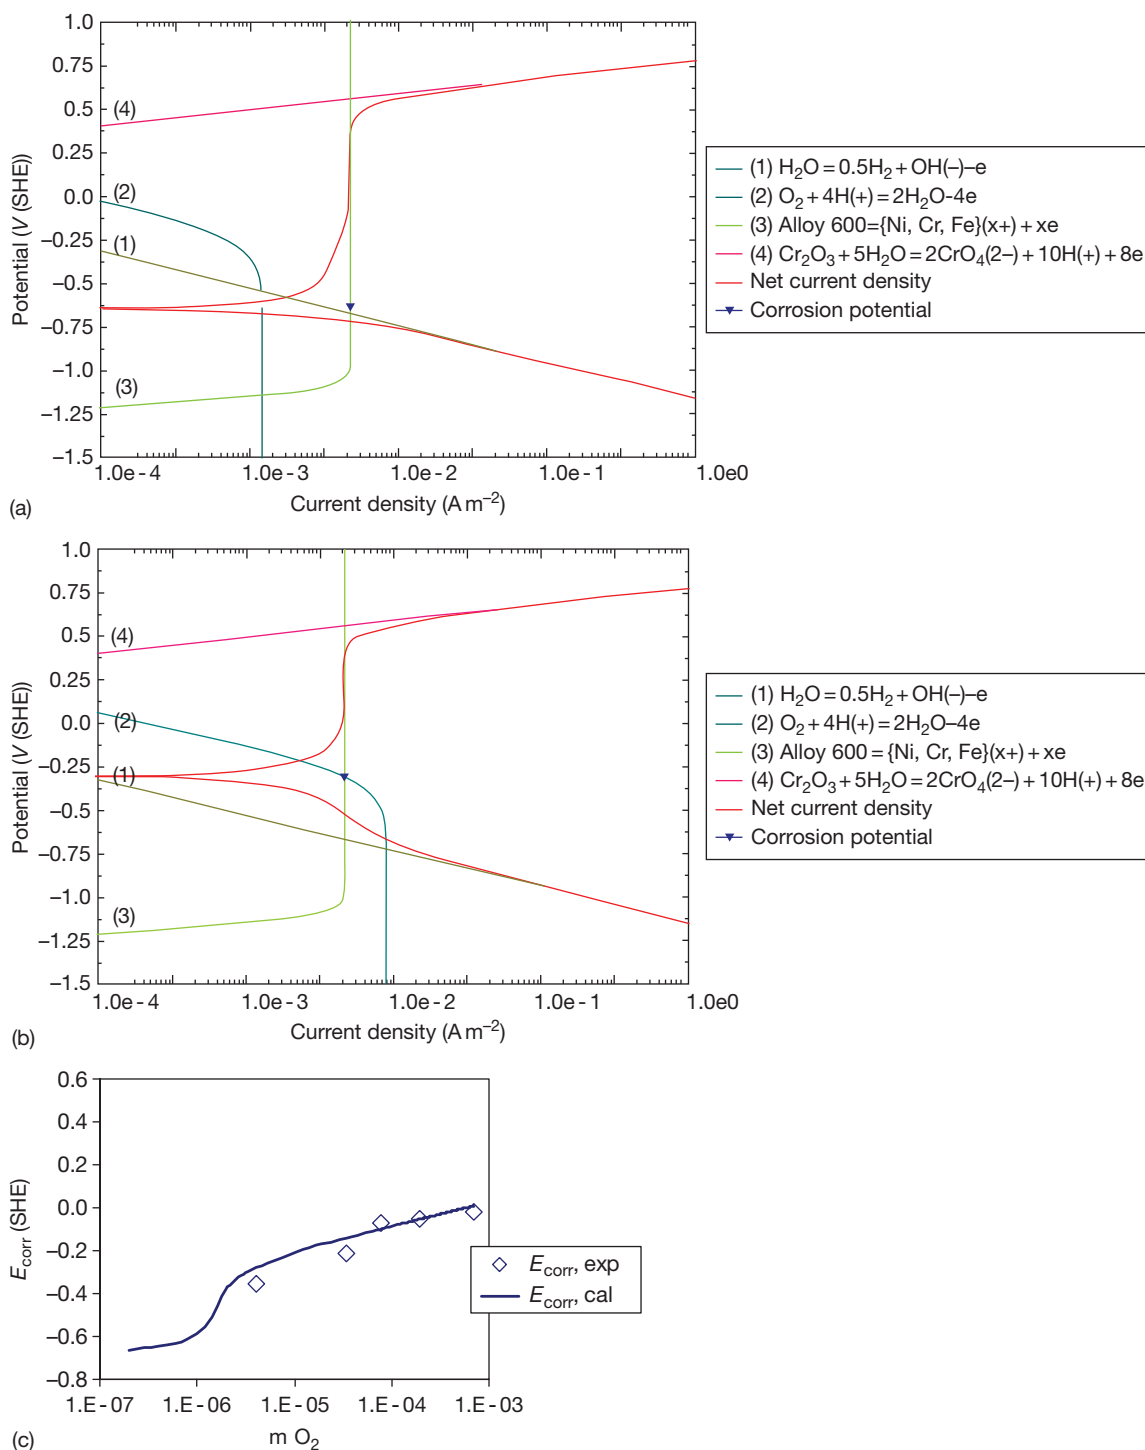

with a corresponding kinetic equation given by

$$i_{\text{p,OH}^-} = k_{\text{OH}^-} a_{\text{OH}^-,s}^c \quad [123]$$

The total passive current density as a function of pH is given by

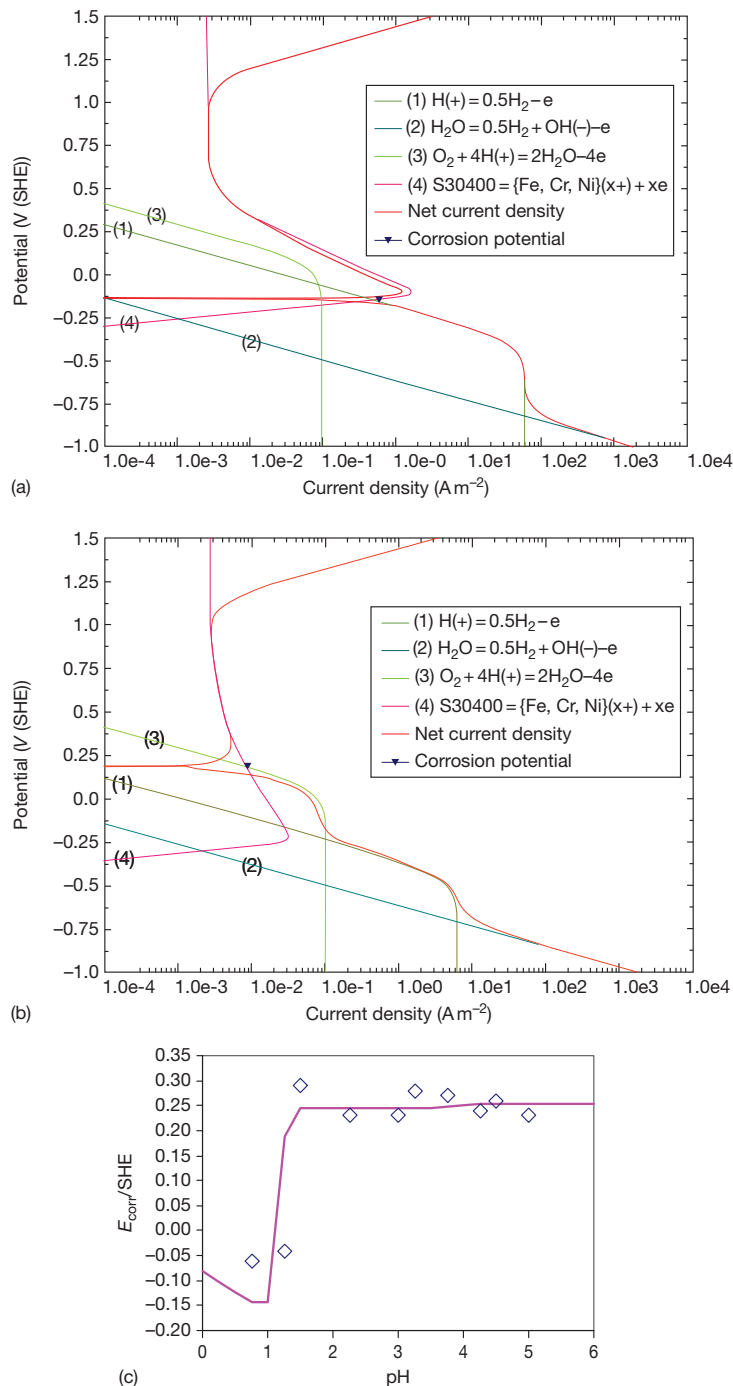

$$i_{\text{p}} = i_{\text{p,H}^+} + i_{\text{p,H}_2\text{O}} + i_{\text{p,OH}^-} \quad [124]$$

It should be noted that the passive dissolution may be influenced by mass transport. For example, aluminum dissolution in alkaline solutions is known to be partly under mass transport control due to the transport of

**Figure 6** Modeling of the corrosion potential of alloy 600 in a 0.1 M LiOH solution at 200 °C as a function of dissolved oxygen concentration. The upper and middle diagrams (a and b) show the calculated partial electrochemical reactions and predicted polarization curve for solutions containing  $4 \times 10^{-7}$  m ( $0.013$  ppm) and  $3 \times 10^{-6}$  m ( $0.096$  ppm)  $O_2$ , respectively. The lower diagram (c) compares the calculated corrosion potential with experimental data<sup>163</sup> at 200 °C as a function of dissolved oxygen molality.

**Figure 7** Electrochemical modeling of the depassivation pH and corrosion potential of type 304 stainless steel in aerated 0.1 M Na<sub>2</sub>SO<sub>4</sub> + H<sub>2</sub>SO<sub>4</sub> solutions. The upper (a) and middle (b) diagrams show the calculated partial electrochemical processes and predicted polarization curve for pH = 0.8 and 1.8, respectively. The lower diagram (c) compares the calculated corrosion potentials with experimental data.<sup>165</sup>

OH<sup>-</sup> ions from the bulk to the interface. Then, the contributions to the passive current density (eqn [124]) should be coupled with mass-transfer equations such as eqn [36].<sup>131</sup>

Figure 7 illustrates the electrochemical modeling of the pH dependence of the active-passive transition of type 304 stainless steel. The upper and middle diagrams in Figure 7 show the partial electrochemical

processes in  $\text{Na}_2\text{SO}_4$  solutions with  $\text{pH}=0.8$  and  $1.8$ , respectively. The anodic curve (line 4) was modeled using a model based on eqns [116] and [117]. The main cathodic process is the reduction of  $\text{O}_2$ . Because of the pH effect on the active–passive transition, the mixed potential moves from the active dissolution region for  $\text{pH}=0.8$  to the passive region for  $\text{pH}=1.8$ . This explains the dependence of the experimentally determined corrosion potential on pH (Figure 7(c)). The pH value at which an abrupt change of  $E_{\text{corr}}$  occurs can be identified with the depassivation pH.

In addition to pH effects, some active ions may influence the magnitude of the passive current density. The effect of active species on the dissolution in the passive state can be modeled by considering surface reactions between the metal oxide film and solution species (Blesa *et al.*,<sup>166</sup> Anderko *et al.*<sup>146</sup>):

where  $X_i$  is the  $i$ th reactive species in the solution, and the subscripts  $a$ ,  $b$ ,  $c_i$  and  $e_i$  represent the reaction stoichiometry. In general, eqn [125] may be written for any active, aggressive, or inhibitive species  $i$  in the solution ( $i=1, \dots, n$ ). It is reasonable to assume that eqn [125] is in quasi-equilibrium. The surface species that forms as a result of reaction eqn [125] may undergo irreversible dissolution reactions such as:

in which dissolved metal species are formed in analogy to those described by eqns [118], [120], and [122]. Mathematical analysis of reactions eqns [125] and [126]<sup>108,146</sup> yields a relationship between the passive current density and activities of reactive species:

$$i_p = i_p^0(\text{pH}) \frac{1 + \sum_i l_i (a_{X_i}^{e_i} / a_{\text{OH}^-}^{e_i})}{1 + \sum_i K_i (a_{X_i}^{e_i} / a_{\text{OH}^-}^{e_i})} \quad [127]$$

where  $i_p^0(\text{pH})$  is given by eqn [124],  $l_i$  is the forward rate of reaction eqn [126], and  $K_i$  is the equilibrium constant of reaction eqn [125].

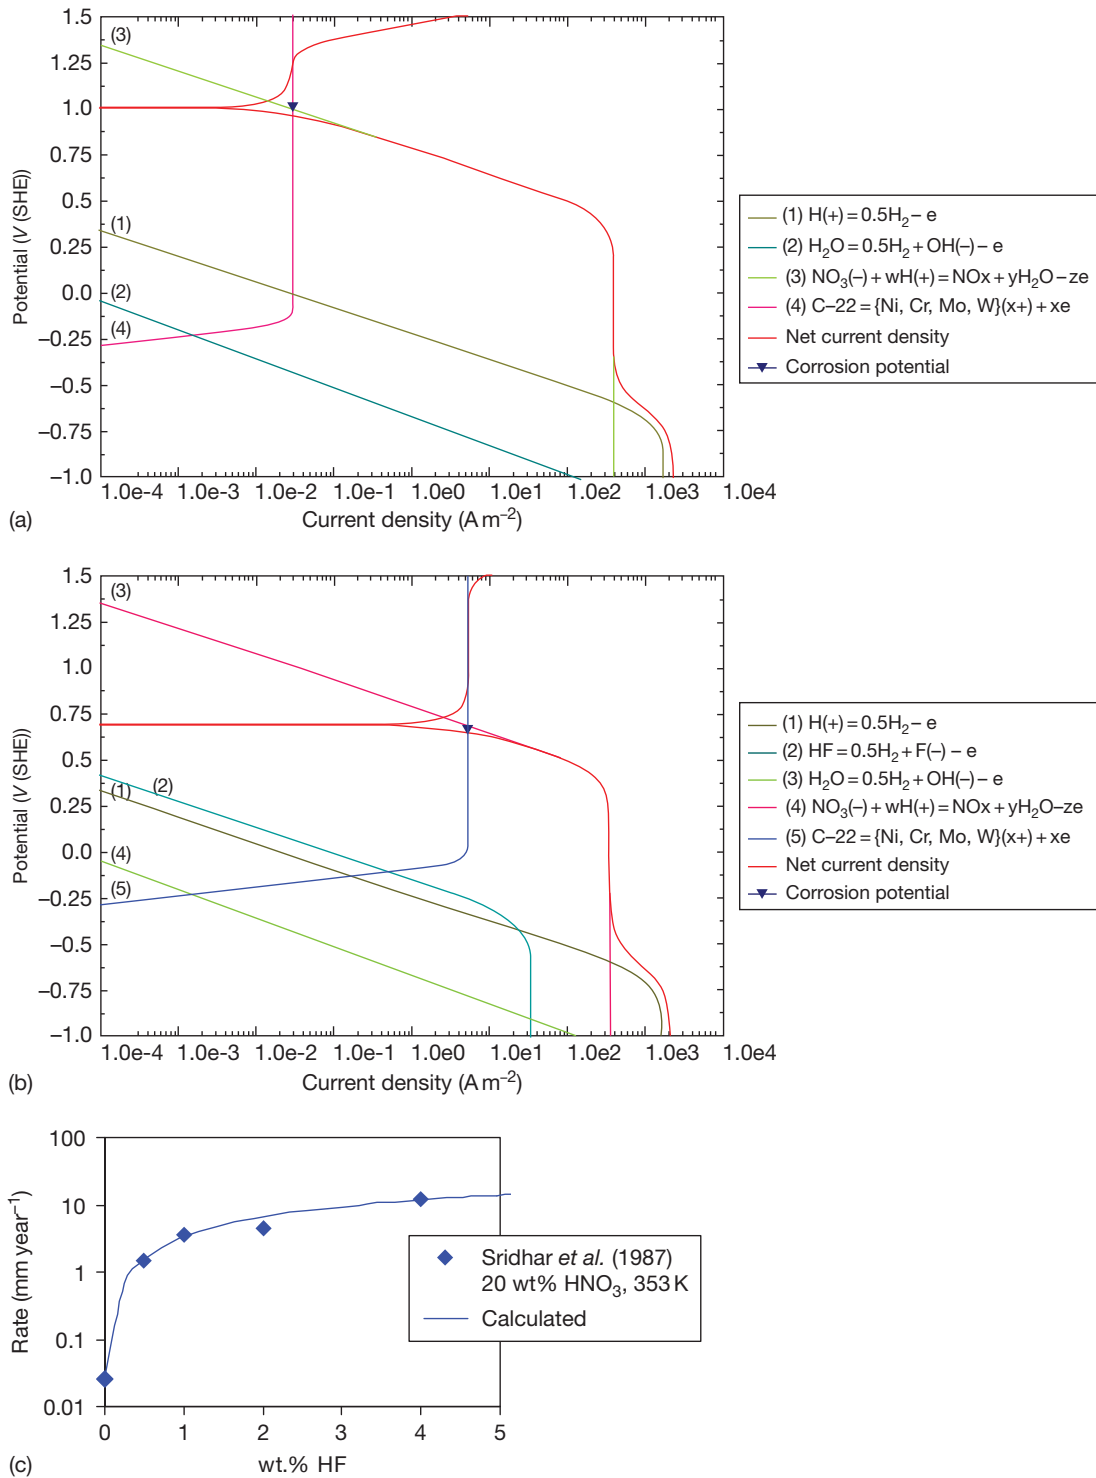

Figure 8 illustrates the effect of active ions on the rate of general corrosion using alloy 22 in mixed  $\text{HNO}_3 + \text{HF}$  solutions as an example. The upper diagram (Figure 8(a)) shows the predicted partial electrochemical processes in a 20%  $\text{HNO}_3$  solution and the middle diagram (Figure 8(b)) shows how

these processes change when a moderate amount of HF (1.57%) is added. A 20 wt.%  $\text{HNO}_3$  solution is an oxidizing medium, and, therefore, reduction of  $\text{NO}_3^-$  ions in an acidic environment is the main cathodic process. This results in a high corrosion potential as shown in Figure 8(a). The corrosion rate is controlled by the dissolution rate of the oxide film. When HF is added, the dissolution rate of the oxide substantially increases even though a moderate amount of HF has practically no effect on the acidity of the system. This effect is reproduced by eqn [127] and manifests itself by the increased passive current density in Figure 8(b). The predicted effects can be compared with the observed corrosion rates in 20%  $\text{HNO}_3$  solution as a function of HF concentration (Figure 8(c)).

### 2.38.3.7 Scaling Effects

In addition to passive dissolution and active–passive transition, modeling of surface scale formation is of great practical importance. Scales form as a result of deposition of corrosion products (e.g., iron carbonate or sulfide) or other solids that reach supersaturation near metal interfaces (e.g., calcareous deposits). Scales can be distinguished from passive films in that they do not give rise to the classical active–passive transition such as that shown in Figure 7. Rather, they reduce the rate of dissolution by providing a barrier to the diffusion of species to and from the surface and by partially blocking the interface, thus reducing the overall rate of electrochemical reactions. In general, there may be multiple mechanisms of scale formation depending on the chemistry of the precipitating solids.

One mechanism of scale formation can be quantified in terms of the competition between the rate of scale formation, which results in the precipitation of a corrosion product, and the rate of corrosion under the scale, which leads to the ‘undermining’ of the scale. When the rate of precipitation exceeds the rate of corrosion, dense protective films are formed. Conversely, when the corrosion rate is greater than the precipitation rate, the scale still forms, but the precipitation rate is not fast enough to fill the growing voids. Then, the scale becomes unprotective even though it may be thick. Nešić and Lee<sup>155</sup> developed a model to represent this phenomenon for  $\text{FeCO}_3$  scale formation. In Nešić and Lee’s<sup>155</sup> model, the local change in the volumetric concentration of the scale-forming solid is given by a redefined eqn [100]:

**Figure 8** Electrochemical modeling of the effect of HF concentration on the corrosion rate of alloy 22 in  $\text{HNO}_3 + \text{HF}$  solutions. The upper (a) and middle (b) diagrams show the partial electrochemical processes in 20 wt%  $\text{HNO}_3$  solutions without HF and with 1.57% HF, respectively. The lower diagram compares the calculated results with experimental data<sup>167</sup> as a function of HF concentration.

$$\frac{\partial c_{\text{solid}}}{\partial t} = R_{\text{solid}} - \text{CR} \frac{\partial c_{\text{solid}}}{\partial z} \quad [128]$$

where the first term on the right-hand side represents the rate of the scale formation and the second term is the scale undermining rate. In eqn [128], CR is the corrosion rate and  $z$  is a direction perpendicular to the surface. The rate of formation of the scale is, in general, a product of the scale particles' surface area-to-volume ratio  $A/V$ , a function of temperature, the thermodynamic solubility product  $K_{\text{sp}}$  and an empirical function of supersaturation  $S$ :

$$R_{\text{solid}} = \frac{A}{V} f(T) K_{\text{sp}} f(S) \quad [129]$$

where supersaturation is defined as

$$S = \frac{\prod a_i^{v_i}}{K_{\text{sp}}} = \frac{\prod c_i^{v_i}}{K_{\text{sp}}} \quad [130]$$

While the  $f(T)$  and  $f(S)$  functions can be, in principle, derived from precipitation kinetics data that are independent of corrosion, Sun and Nešić<sup>168</sup> have determined that much more reliable precipitation rates can be obtained from corrosion weight loss and gain measurements than from kinetic measurements that start from dissolved metal ions. The  $A/V$  ratio depends on the porosity of the scale on the metal surface. Nešić and Lee<sup>155</sup> developed an empirical function of porosity that is consistent with the experimental data for  $\text{FeCO}_3$  scale formation.

A different model is necessary for scales whose formation does not follow the kinetics of precipitation processes. For example,  $\text{FeS}$  scales form very fast in highly undersaturated solutions, in which they would be thermodynamically unstable in the bulk, and their formation appears not to be influenced by solution supersaturation. Thus, the effect of  $\text{FeS}$  scales can be modeled by assuming a solid-state reaction at the metal surface that is mediated by the adsorption of  $\text{H}_2\text{S}$  (Anderko and Young,<sup>169</sup> Nešić *et al.*<sup>170</sup>) The formation of  $\text{FeS}$  scales is further complicated by the existence of an outer layer that results from the growth, cracking, and delamination of the  $\text{FeS}$  film. A model that accounts for these phenomena was developed by Sun and Nešić.<sup>171</sup>

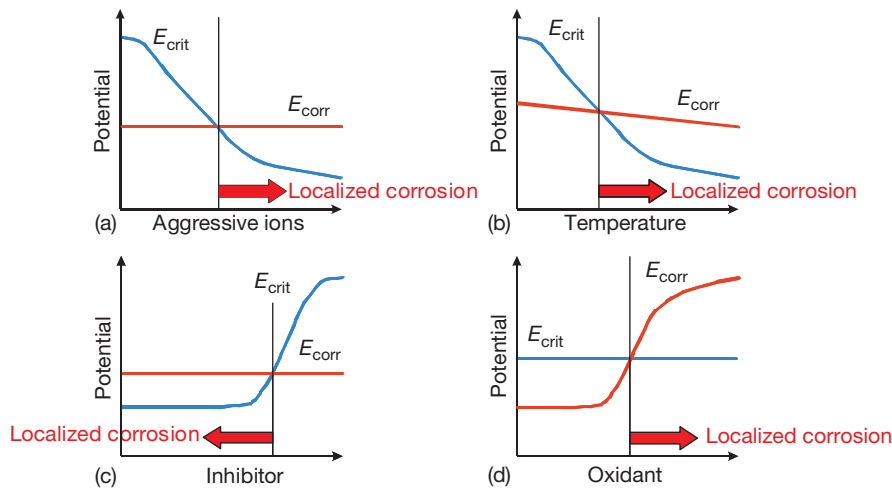

### 2.38.3.8 Modeling Threshold Conditions for Localized Corrosion

Modeling of the evolution of localized corrosion has been the subject of extensive research during the past three decades, and a number of important models have been developed for the initiation, stabilization,

propagation, and stifling of individual pits, crevices, and cracks and for the statistical behavior of their ensembles in corroding structures. However, this topic is outside the scope of this chapter and will be reviewed in the chapter 'Predictive Modeling of Corrosion' in this volume.

In this chapter, we focus solely on models that predict the conditions for the occurrence of localized corrosion without going into the treatment of the evolution of localized corrosion events in time and space. Such models are designed to find the threshold criteria for localized corrosion. In general, localized corrosion occurs when the corrosion potential of an alloy in a given environment exceeds a critical potential. The meaning, experimental determination, and interpretation of the key potentials that characterize localized corrosion have been reviewed by Szklarska-Smialowska.<sup>172</sup> While this general concept is well accepted, what constitutes a critical potential continues to be debated. The selection of the critical potential depends on the particular phenomenon that is to be modeled.

The applicability of the critical potential concept to modeling localized corrosion is qualitatively illustrated in Figure 9. In this figure, the arrows indicate the conditions at which localized corrosion is expected. For a given alloy, the critical potential decreases with an increase in the concentration of aggressive species (e.g., halide ions) as shown in Figure 9(a). The shape of the  $E_{\text{crit}}$  curve corresponds to that of the repassivation potential curve, but the qualitative pattern is more general. Unlike the critical potential, the corrosion potential is usually not a strong function of aggressive ion concentration unless significant localized corrosion occurs. The critical aggressive species concentration for localized corrosion is observed when  $E_{\text{corr}}$  exceeds  $E_{\text{crit}}$ . Similarly, for a given aggressive chemical environment, a critical temperature exists (see Figure 9(b)). The critical potential is also strongly affected by the presence of inhibitors. As shown in Figure 9(c), this gives rise to a critical inhibitor concentration. In many environments, the presence of oxidants may increase  $E_{\text{corr}}$  so that localized corrosion may occur beyond a critical concentration of redox species (Figure 9(d)). The actual conditions in a system may be a combination of the four idealized cases shown in Figure 9. Thus, the key is to predict both the corrosion potential and the repassivation potential. The corrosion potential can be obtained from a general-corrosion, mixed-potential model for passive metals as described above. For the critical potential, separate models are necessary.

**Figure 9** A general conceptual scheme of the use of the corrosion potential ( $E_{\text{corr}}$ ) and critical potential ( $E_{\text{crit}}$ ) to predict the effect of aggressive ions, temperature, inhibitors, and oxidizing redox species on localized corrosion. The arrows marked 'localized corrosion' denote the potential ranges in which localized corrosion can be expected.

In this chapter, we briefly review the computation and applicability of the passivity breakdown potential and the repassivation potential.

### 2.38.3.8.1 Breakdown of passivity

To predict the initiation of localized corrosion, it is necessary to calculate the critical passivity breakdown potential. Several theories have been developed to relate the breakdown potential to the concentration of aggressive species in the solution (Heusler and Fischer,<sup>173</sup> Strehblow and Titze,<sup>174</sup> Lin *et al.*,<sup>175</sup> Okada,<sup>176</sup> McCafferty,<sup>177</sup> Haruna and Macdonald,<sup>178</sup> Macdonald,<sup>97</sup> Yang and Macdonald,<sup>179</sup> and papers cited therein). A common theoretical result, confirmed by experimental data, is the linear dependence of the passivity breakdown potential on the logarithm of the concentration of aggressive ions. While this observation is generally accepted, its generalization to systems with multiple aggressive and inhibitive ions is not immediately obvious.

A particularly comprehensive treatment of passivity breakdown is provided by the point defect model of Macdonald and coworkers (Lin *et al.*,<sup>175</sup> Haruna and Macdonald,<sup>178</sup> Macdonald,<sup>97</sup> Yang and Macdonald<sup>179</sup>). According to the point defect model, passivity breakdown results from the condensation of cation or metal vacancies at the interface between the metal and the passive barrier layer. The vacancies are envisaged to be generated at the barrier layer–solution interface in an autocatalytic, anion-induced process. For systems containing only aggressive (halide) ions  $X$ , the critical breakdown potential is expressed as

$$E_b = \frac{4.606RT}{\chi\alpha F} \log \left[ \frac{\mathcal{J}_m}{\hat{a}Du^{-\chi/2}} \right] - \frac{2.303RT}{\alpha F} \log a_X \quad [131]$$

where  $\mathcal{J}_m$  is the rate of annihilation of cation vacancies at the metal/barrier layer interface,  $\hat{a}$  and  $u$  are thermodynamic parameters related to the absorption of an aggressive ion into an oxygen vacancy,  $D$  is the cation vacancy diffusivity, and  $\alpha$  is the polarizability of the film–solution interface. Yang and Macdonald<sup>179</sup> extended eqn [131] to systems containing both aggressive ions  $X^-$  and inhibitive ions  $Y^{z-}$ :

$$E_b = E_b^0 - \frac{\beta}{\alpha} \text{pH} - \frac{2.303}{\alpha\alpha_0 F} \log \frac{a_{X^-}}{a_{Y^{z-}}} \quad [132]$$

where the constant  $E_b^0$  is a function of adsorption and elementary reaction rate parameters that is derived from a competitive adsorption model for the  $X^-$  and  $Y^{z-}$  species,  $\beta$  is the dependence of the potential drop across the barrier layer–solution interface on pH, and  $\alpha_0$  is a transfer coefficient. The predictions of the point defect model have been found to be in agreement with experimental phenomena including the linear dependence of the breakdown potential on the concentrations of aggressive and inhibitive ions, the dependence of the induction time on potential and chloride concentration, dependence of the breakdown potential on the scan rate and the inhibition of pitting by Mo and W in the alloy. It should be noted that the breakdown potential is a distributed quantity that can be described with a normal distribution function. The distribution in  $E_b$  has been reproduced by assuming that the cation diffusivity is normally distributed.<sup>97</sup>

While the logarithmic dependence of the breakdown potential on the aggressive species concentration is predicted by most passivity breakdown models, the induction time provides a more stringent criterion for testing alternative models. Accordingly, Milošev *et al.*<sup>180</sup> tested the validity of the point defect model, the two-dimensional nucleation model of Heusler and Fischer,<sup>173</sup> and the halide nuclei model of Okada<sup>176</sup> for the pitting of copper. The point defect model was found to yield the best agreement with experimental data.

### 2.38.3.8.2 Repassivation potential and its use to predict localized corrosion

While the breakdown potential is the critical parameter for the initiation of pitting, the repassivation potential ( $E_{rp}$ ) has been used for predicting the long-term occurrence of pitting and crevice corrosion. The repassivation potential (also called protection potential) is the potential at which a stably growing pit or crevice corrosion will cease to grow. Thus, localized corrosion cannot occur at potentials below  $E_{rp}$ . The use of  $E_{rp}$  for engineering predictions can be justified by the fact that only the fate of stable pits or crevice corrosion is important for predicting the possibility of failure, and metastable pits do not adversely affect the performance of engineering structures. It has been shown by Dunn *et al.*<sup>181,182</sup> that  $E_{rp}$  is practically independent of the amount of charge passed in a localized corrosion process as long as it is above a certain minimum amount of charge. As a result, the repassivation potential is relatively insensitive to prior pit depth and surface finish. As a corollary, it has been shown that the repassivation potential for pitting (i.e., measured on an open sample) and the repassivation potential for crevice corrosion (i.e., measured on a creviced sample) coincide at high pit depths. This has demonstrated the utility of the repassivation potential for engineering design as it provides a reproducible and inherently conservative threshold for the occurrence of localized corrosion. Thus, the prediction of long-term occurrence of localized corrosion can be separated into two independent parts, that is, the calculation of the repassivation and the corrosion potentials. The separation of localized corrosion modeling into these two steps is valid as long as the initial stages of stable localized corrosion are considered because the corrosion potential is not affected at this stage by the progress of the localized corrosion process and the interaction between pits can be ignored. The separation remains valid as long as significant pit or crevice corrosion growth does not occur and the area of an actively

corroding pit does not become significant compared to the overall area.

A model for calculating the repassivation potential has been developed by Anderko *et al.*<sup>183</sup> by considering the electrochemistry of a metal M that undergoes dissolution underneath a layer of concentrated metal halide solution MX. The concentrated solution may or may not be saturated with respect to a hydrous solid metal halide. In the process of repassivation, a thin layer of oxide forms at the interface between the metal and the hydrous metal halide. The model assumes that, at a given instant, the oxide layer covers a certain fraction of the metal surface. This fraction increases as repassivation is approached. Further, the model includes the effects of multiple aggressive and nonaggressive or inhibitive species, which are taken into account through a competitive adsorption scheme. The aggressive species form metal complexes, which dissolve in the active state. On the other hand, the inhibitive species and water contribute to the formation of oxides, which induce passivity. The model assumes that the measurable potential drop across the interface can be expressed as a sum of four contributions, that is

$$E = \Delta\Phi_{M/MX} + \Delta\Phi_{MX} + \Delta\Phi_{MX/S} + \Delta\Phi_S \quad [133]$$

where  $\Delta\Phi_{M/MX}$  is the potential difference at the interface between the metal and metal halide, which may be influenced by the partial coverage by the metal oxide,  $\Delta\Phi_{MX}$  is the potential drop across the hydrous halide layer,  $\Delta\Phi_{MX/S}$  is the potential difference across the metal halide–solution interface, and  $\Delta\Phi_S$  is the potential drop across the boundary layer within the solution. Expressions for the potential drops can be derived using the methods of nonequilibrium thermodynamics.<sup>184</sup> In general, these expressions are complex and can be solved only numerically. However, a closed-form equation has been found in the limit of repassivation, that is, when the current density reaches a predetermined low value  $i_{rp}$  (typically  $i_{rp} = 10^{-2} \text{ A m}^{-2}$ ) and the fluxes of metal ions become small and comparable to those for passive dissolution. Then, eqn [133] can be used to arrive at a closed-form expression for the repassivation potential. This closed-form expression, which can be solved numerically to calculate  $E_{rp}$  is given by:

$$1 + \sum_k \left[ \left( \frac{i_{rp}}{i_p} - 1 \right) \frac{l_k''}{i_{rp}} \theta_k^{n_k} \exp\left(\frac{\zeta_k F E_{rp}}{RT}\right) \right] = \sum_j \frac{k_j''}{i_{rp}} \theta_j^{n_j} \exp\left(\frac{\alpha_j F E_{rp}}{RT}\right) \quad [134]$$

where  $i_p$  is the passive current density,  $T$  is the temperature,  $R$  is the gas constant, and  $F$  is the Faraday constant. The partial coverage fraction of a species  $j$  is related to the activity of this species in the bulk solution by

$$\theta_j = \frac{K_{\text{ads},j} a_j}{1 + \sum_k K_{\text{ads},k} a_k} \quad [135]$$

where

$$K_{\text{ads},j} = \exp\left(-\frac{\Delta G_{\text{ads},j}}{RT}\right) \quad [136]$$

and  $\Delta G_{\text{ads},j}$  is the Gibbs energy of adsorption. The parameters  $k'_j$  and  $l''_k$  in eqn [134] are rate constants for surface reactions mediated by the adsorption of aggressive and inhibitive species, respectively. The inhibitive species include water, as it is necessary for oxide formation. The parameter  $n_j$  is the reaction order with respect to species  $j$ , and  $\alpha_j$  and  $\xi_k$  are the electrochemical transfer coefficients for reactions mediated by aggressive and inhibitive species, respectively. Some parameters ( $\Delta G_{\text{ads},i}$ ,  $\alpha_j$ , and  $n_k$ ) can be assigned default values. The remaining parameters need to be regressed from a limited amount of experimental  $E_{\text{rp}}$  measurements. Since  $E_{\text{rp}}$  data are most abundant for chloride solutions, the rate constant for the chloride ions ( $k'_{\text{Cl}}$ ), reaction order with respect to chlorides ( $n_{\text{Cl}}$ ), rate constant for water ( $l''_{\text{H}_2\text{O}}$ ), and electrochemical transfer coefficient for water ( $\xi_{\text{H}_2\text{O}}$ ) are determined based on the data for chloride solutions. The determination of parameters is greatly simplified by the fact that the parameters for Fe–Ni–Cr–Mo–W–N alloys can be correlated with alloy composition,<sup>185,186</sup> thus enhancing the predictive value of the model. The  $k'_j$  and, if necessary,  $n_j$  parameters are determined for other aggressive species  $j$  (e.g., bromide ions) using  $E_{\text{rp}}$  data for either pure or mixed

solutions containing such ions. Finally, the  $l''_k$  parameters for inhibitive ions  $k$  are determined on the basis of data for mixed solutions containing chlorides and inhibitors. Data for mixed systems are necessary because  $E_{\text{rp}}$  is undefined in solutions containing only inhibitors.

The repassivation potential model has a limiting character, that is, it accurately represents the state of the system in the repassivation potential limit. In addition to the value of the repassivation potential, the model predicts the correct slope of the current density versus potential relationship as the potential deviates from  $E_{\text{rp}}$ .<sup>183</sup> The current density predicted by the model as a function of potential is given by

$$i = \frac{\sum_j k'_j \theta_j^{n_j} \exp\left(\frac{\alpha_j FE}{RT}\right) + \sum_j l''_j \theta_j^{n_j} \exp\left(\frac{\xi_j FE}{RT}\right)}{1 + \frac{1}{i_p} \sum_j l''_j \theta_j^{n_j} \exp\left(\frac{\xi_j FE}{RT}\right)} \quad [137]$$

Equation [137] reduces to eqn [134] for  $E = E_{\text{rp}}$  and  $i = i_{\text{rp}}$ . Since eqn [137] is a limiting law, its accuracy gradually deteriorates as the potential increasingly deviates from  $E_{\text{rp}}$ . Equation [137] cannot be regarded as a model for the propagation rate of an actively growing pit or crevice because it does not take into account the factors such as the ohmic potential drop, transport limitations, and so on. However, the current density predicted using eqn [137] for  $E > E_{\text{rp}}$  is useful because it provides an estimate of the maximum propagation rate of an isolated pit as a function of potential. Such an upper estimate is convenient because it relies only on parameters that are calibrated using repassivation potential data.

Figure 10 shows the application of the repassivation potential model to alloy CuNi 7030 in chloride

**Figure 10** Modeling the repassivation potential of alloy CuNi 7030 (UNS C71500).<sup>217</sup> as a function of chloride activity at various temperatures.

solutions at three temperatures. As shown in the figure, the slope of the repassivation potential changes as a function of chloride activity. A steeper slope is observed at low chloride concentrations. This is a general phenomenon for alloys and becomes more pronounced for more corrosion-resistant alloys.<sup>183</sup> The transition between the low-slope and high-slope segments of the curves strongly depends on the alloy and temperature.

A particularly useful application of the repassivation potential model is for investigating the competing effects of aggressive and inhibitive species. For example, Figure 11 shows the inhibitive effect of nitrate ions on localized corrosion of alloy 22 in concentrated chloride solutions. The  $E_{rp}$  versus  $\text{NO}_3^-$  concentration curves have a characteristic shape with two distinct slopes. As the concentration of the  $\text{NO}_3^-$  ions is increased, the slope of the  $E_{rp}$  versus  $\text{NO}_3^-$  concentration curve initially slowly increases with a low slope. At a certain concentration of  $\text{NO}_3^-$ , the slope of the  $E_{rp}$  curve rapidly increases and the repassivation potential attains a high value. At  $\text{NO}_3^-$  concentrations that lie beyond the high-slope portion of the  $E_{rp}$  versus  $\text{NO}_3^-$  curve, localized corrosion becomes impossible even in systems with a high corrosion potential. Thus, there is a fairly narrow range of inhibitor concentrations over which the  $E_{rp}$  curve transitions from a low-slope region (in which localized corrosion is possible depending on the value of the corrosion potential) to a high-slope region that constitutes the upper limit of inhibitor concentrations for localized corrosion. The exact location of the transition region depends on the temperature and chloride concentration and can be accurately reproduced using the repassivation potential model.

**Figure 11** Modeling the effect of nitrate ions on the repassivation potential of alloy 22 in concentrated chloride solutions. The experimental data are from Dunn *et al.*<sup>187</sup>

Figure 12 illustrates an application of the corrosion potential and repassivation potential models to predict the critical crevice temperature. At temperatures below critical crevice temperature (CCT), the calculated corrosion potential ( $E_{corr}$ ) should lie below the repassivation potential, whereas it should exceed  $E_{rp}$  above CCT. Thus, the intersection of the  $E_{corr}$  and  $E_{rp}$  curves versus temperature provides an estimate of CCT. Figure 12 shows the results of such calculations for alloy C-276 in 6%  $\text{FeCl}_3$  solutions.<sup>188</sup> The repassivation potential shows an initially steep decrease followed by a moderate decrease at higher temperatures. On the other hand, the corrosion potential shows a much weaker temperature dependence. The intersection points of the  $E_{corr}$  and  $E_{rp}$  curves can be compared with experimental critical crevice temperatures (Hibner<sup>189</sup>).

It should be noted that while the approach based on computing  $E_{corr}$  and  $E_{rp}$  can predict the long-term occurrence and maximum propagation rate of localized corrosion, it gives no spatial or temporal information. For predicting the spatial and temporal evolution of localized corrosion, models are required that include a detailed treatment of mass transport and take into account the geometric constraints of crevices, pits, and so on. Such models are outside the scope of this chapter.

### 2.38.3.9 Selected Practical Applications of Aqueous Corrosion Modeling

In this section, we briefly outline selected models that have been developed for practical applications on the basis of the principles discussed above.

Extensive efforts have been devoted to the modeling of aqueous corrosion in oil and gas environments.

**Figure 12** Prediction of the critical crevice temperature (CCT) for various alloys in a 6%  $\text{FeCl}_3$  solution using corrosion potential and repassivation potential models.<sup>188</sup> The vertical lines show the location of the experimental CCT values.<sup>189</sup> The intersection of the calculated corrosion potential and repassivation potential lines shows the predicted critical crevice temperature.

This is due to the great practical importance of corrosion in oil and gas production and transmission, and to the fact that the number of key corrosive components in such environments is relatively limited (primarily to  $\text{CO}_2$ ,  $\text{H}_2\text{S}$ , acetic acid, and  $\text{O}_2$ ), thus making the modeling task manageable despite the inherent complexity of corrosion mechanisms and their dependence of flow conditions. Corrosion modeling in this area has been reviewed by Nešić *et al.*,<sup>190</sup> Nyborg,<sup>191</sup> and Papavisanam *et al.*<sup>192–194</sup> The  $\text{CO}_2/\text{H}_2\text{S}$  models range from expert systems based on laboratory and field data to mechanistic models that recognize the partial electrochemical processes in an explicit way. Among the electrochemical models, the treatment of flow effects using mass transfer coefficients has found wide applicability for both single-phase and two-phase flow (Nešić *et al.*,<sup>115</sup> Dayalan *et al.*,<sup>195</sup> Anderko and Young,<sup>169</sup> Pots and Kapusta,<sup>196</sup> Deng *et al.*<sup>197</sup>). While the methodology for modeling  $\text{CO}_2$  corrosion is well established, the modeling of  $\text{H}_2\text{S}$  effects is still in a state of flux and is a subject of significant research efforts (Anderko and Young,<sup>169</sup> Nešić *et al.*,<sup>170</sup> Sun and Nešić<sup>171</sup>). A  $\text{CO}_2$  corrosion model based on a detailed treatment of transport (eqns [100]–[103]) has been developed by Nordsveen *et al.*,<sup>116</sup> Nešić *et al.*,<sup>198</sup> and Nešić and Lee.<sup>166</sup> This model has been further extended to  $\text{CO}_2/\text{H}_2\text{S}$  corrosion by considering mechanistic aspects of  $\text{FeS}$  scale formation (Nešić *et al.*,<sup>170</sup> Sun and Nešić<sup>171</sup>). The model has been integrated with a multiphase flow model, which made it possible to predict the effect of water entrainment and water wetting in oil–water

systems (Nešić *et al.*<sup>170</sup>). Also, a stochastic algorithm for predicting localized corrosion due to partially protective  $\text{FeCO}_3$  scales has been integrated with this model (Nešić *et al.*<sup>199</sup>).

Another area in which electrochemical models have found wide applicability is the prediction of the corrosion potential in dilute aqueous solutions that exist in power generation industries. In particular, mixed-potential models have been developed for stainless steels in water as a function of oxygen and hydrogen content (Macdonald,<sup>161</sup> Lin *et al.*,<sup>138</sup> Kim<sup>103</sup>). Such models are useful for calculating  $E_{\text{corr}}$  in boiling water reactors and related environments.  $E_{\text{corr}}$  is then further used for localized corrosion modeling. In such systems, modeling of the initiation and evolution of crevice corrosion, stress corrosion cracking, and corrosion fatigue is of primary importance. For this purpose, several electrochemical models that are suitable for alloys in high temperature and low-conductivity water have been developed (see Betts and Boulton,<sup>200</sup> Turnbull,<sup>201–203</sup> Engelhardt *et al.*<sup>204,205</sup> and references therein).

Corrosion in halide-containing natural and industrial environments such as seawater, deliquescent liquids, or production brines is another important application for modeling. For example, King *et al.*<sup>123</sup> developed a model for calculating the corrosion potential of copper in aerated chloride solutions. Anderko and Young<sup>108</sup> modeled general corrosion of steel in concentrated bromide brines used in absorption cooling. Sridhar *et al.*<sup>131</sup> developed a model that predicts both the general corrosion and the occurrence of localized corrosion for stainless steels and aluminum in seawater. A mixed-potential model has been developed to predict the behavior of nuclear fuel in steel containers (Shoesmith *et al.*<sup>206</sup>). Models for the initiation, stabilization, and propagation of pitting, crevice corrosion, and cracking in halide systems have been developed by a number of authors (Turnbull and Ferris,<sup>207</sup> Turnbull,<sup>203,208</sup> Betts and Boulton,<sup>200</sup> Engelhardt *et al.*,<sup>209,210</sup> Cui *et al.*,<sup>211</sup> and references therein).

Modeling corrosion in the process industries is a potentially fruitful area but is subject to great difficulties because of the complex and variable nature of the chemical environments. In principle, acid systems are amenable to modeling because of their well-defined chemistry. In particular, corrosion in acids has been modeled by Sridhar and Anderko<sup>212</sup> in the moderate concentration range. Rahmani and Strutt<sup>213</sup> developed a model for very concentrated sulfuric acid solutions, in which corrosion can be assumed to

be exclusively under mass transport control. Veawab and Arronwilas<sup>214</sup> developed a model for the general corrosion in amine-CO<sub>2</sub> systems. Models are also available for the corrosivity in wet porous media (Huet *et al.*<sup>215</sup>). Anderko *et al.*<sup>216</sup> applied the localized corrosion model based on calculating the repassivation and corrosion potentials to predict the occurrence of pitting and estimate the worst-case propagation rates of localized corrosion in a process environment.

### 2.38.4 Concluding Remarks

Over the past three decades, tremendous progress has been achieved in the development of computational models of aqueous corrosion. A number of practically important models have been developed for applications as diverse as oil and gas production and transmission, nuclear and fossil power generation, seawater service, and various chemical processes.

Thermodynamic models of electrolyte systems have reached a level of sophistication that extended their applicability range from dilute aqueous solutions to multiphase, multicomponent systems ranging from infinite dilution to solid saturation or pure solute limits. Although they were originally developed mostly for applications other than corrosion (especially chemical processing and geology), they are increasingly used to predict the solution chemistry of corrosive environments and to understand the effect of phase behavior on corrosion. Electrochemical models of corroding interfaces have been developed to predict the kinetics of anodic and cathodic reactions that are responsible for corrosion and to relate them to bulk solution chemistry and flow conditions. Semiempirical and mechanistic models of passivity have been developed to predict the behavior of passive metals and the breakdown of passivity. Also, models are available to predict the threshold conditions for localized corrosion.

The main focus of the models reviewed in this chapter is on relating the chemistry of the environment to electrochemical corrosion phenomena on metal surfaces. However, this is often only the first stage of corrosion modeling. Beyond this stage, the models discussed here serve as a basis for simulating the spatial and temporal evolution of localized and general corrosion damage in various engineering structures subject to localized and general corrosion. This level of modeling will be discussed in other chapters of this volume.

### 2.40.1 Introduction

The reliable prediction of corrosion behavior is a fundamental requirement for the effective control of corrosion. At first sight, this is relatively easy. There is an extensive corrosion literature, and we can simply look up the relevant information. Unfortunately, real world corrosion never seems to involve quite the same conditions as have been tested before, and there is also the difficult question of the inherent variability of the corrosion process. If we are concerned with only one variable such as the effect of temperature on the corrosion of a particular grade of stainless steel in a specific concentration of sulfuric acid, we can plot all the data that we can find and estimate the behavior for the temperature that we are interested in. However, this approach is limited. If we are interested in 22% H<sub>2</sub>SO<sub>4</sub>, we shall find very few data points, such that we shall probably not be able to plot a reasonable curve. We can extend the number of points available by considering a spread of values, but even then we shall be using only a very small fraction of the relevant data available.

However, in the particular case where we do have a large collection of information, we need techniques to make efficient use of that information. In this chapter, we are concerned with techniques that rely only on the available data. It is important to appreciate that such techniques are necessarily limited to conditions

that lie within the region for which we have data. In order to extrapolate outside the range of the available data, we need to use techniques that take advantage of the knowledge of the controlling processes.

### 2.40.2 Interpolation Techniques

In its simplest form, the problem is one of interpolation. Given the data for points around the point that we are interested in, how do we estimate data for our point? For one or two variables, it is relatively easy to plot graphs, fit lines or surfaces to the graph, estimate standard error and so forth. However, in corrosion, we generally need to consider more than two controlling variables. Even for the very simple case of austenitic stainless steels corroding in sulfuric acid, our data set has a minimum of six controlling variables (Cr, Ni, and Mo content of the steel, temperature and concentration of the acid, and flow conditions). We could easily and justifiably increase the number of variables, for example, by considering minor alloying elements, such as sulfur, phosphorus, and carbon. In the absence of a good model of the behavior, it is difficult to know which variables are significant. If we ignore the effects of significant variables, we introduce uncertainty into the prediction; if we reject data that do not have the ‘correct’

\*This article is based on a paper originally published in *Materials and Design*.<sup>1</sup>

values of parameters, we ignore much of the information contained within our data set.

We therefore need interpolation methods that can accommodate large numbers of input variables. The most obvious approach is to assume that the corrosion rate ( $y$ ) depends linearly on the  $n$  controlling variables ( $x_1, x_2, \dots, x_n$ ) and that the effects of the variables are independent.

Then, we can write

$$y = a_0 + a_1x_1 + a_2x_2 + \dots + a_nx_n$$

where  $a_0$  to  $a_n$  are coefficients that we must estimate from the available data.

This approach is quite widely used, and provided we have more data points than controlling variables, it is relatively easy to find the values of  $a_0$  to  $a_n$  that minimize the error, using techniques of regression analysis. Unfortunately, the underlying assumptions are rather questionable. Corrosion rate often has a rather non-linear dependence on the controlling variables, and the effects of the variables are rarely independent. In theory, we can reduce this limitation by fitting higher-order functions, for example, the second-order function

$$y = a_0 + a_1x_1 + a_2x_2 + \dots + a_nx_n + a_{11}x_1^2 + a_{12}x_1x_2 + \dots + a_{1n}x_1x_n + \dots + a_{nn}x_n^2$$

Note, however, that the second-order function has a large number of coefficients (for  $n = 6$ , there are 28 coefficients) and the second-order function is not

particularly flexible (in one dimension, it is a quadratic). We can get more flexibility by using higher-order functions, but the number of coefficients involved increases markedly.

A better approach is to use rather more flexible functions that can adapt to the data, and thereby fit it better with fewer coefficients. In effect, this is the approach used by artificial neural networks (so-called because they are based on simplified models of animal nervous systems). However, we tend not to describe the artificial neural network by the function that is used to model the data, because the overall function used is very complicated. Rather, we describe the neural network as an assembly of connected components, where each component implements a somewhat simpler function. The components are known as nodes or neurons, and each node has one or more inputs and one output. Several transfer functions can be used for the nodes, but a common one is the sigmoidal function (see [Figure 1](#)):

$$y = \frac{1}{1 + (1/\exp x')}$$

where  $x' = a_0 + a_1x_1 + \dots + a_nx_n$ . Then a neural network is constructed by assembling nodes in a network. In principle, the network can be arbitrarily complex, but in practice we generally use fairly simple layered structures, such as that shown in [Figure 2](#). Each node of the network takes a number of inputs; each input value ( $x_1$  to  $x_n$ ) is multiplied by a weight

**Figure 1** Sigmoidal transfer function typically used by neural network nodes or neurons.

**Figure 2** Layered structure of typical artificial neural network.

( $a_1$  to  $a_n$ ) and the sum of all the weighted inputs plus a bias ( $a_0$ ) is used as the input ( $x'$ ) to the sigmoidal function.

As with simpler linear and polynomial functions, the problem is then to find the values of the coefficients that give the 'best' fit between the output of the neural network and the known data. Owing to the complexity of the function implemented by the neural network, we cannot define an analytical method to find the coefficients, and a range of heuristic methods are used to search for the values of the coefficients that give the best fit, usually starting from randomized values. The process of seeking the coefficients is known as 'training' the network (by analogy with the training of biological neural networks).

It is important to appreciate the limitations of neural network methods:

- Neural networks cannot produce reliable predictions for input conditions that are a long way from the data used to train them. The precise meaning of 'a long way' in this context is rather difficult to define, but it is clear that extrapolation beyond the bounds of the training data is unlikely to be reliable (except by good luck).
- If there are insufficient training data for the complexity of the network, the network may 'learn' the individual data points very precisely, but the behavior between the training points will be unpredictable. It has been suggested that there should always be more training points than weights in the network in order to avoid this problem. While this seems plausible, the rule has often been broken, apparently without problems. However, it is difficult to inspect the multidimensional function implemented by the network, and it may therefore be the case that problems with the fit produced by the network have simply not been detected.
- Neural networks are purely phenomenological and do not inherently produce a mechanistic understanding of the process being modeled. However, the generalization of the behavior that is

achieved with a well-fitted neural network may well contribute to the development of mechanistic understanding.

- Large training data sets are required, especially when the data are noisy (it might be considered that this should advise against their use to model corrosion processes).

The training of a neural network involves the iterative refinement of the weights for all of the nodes. Typically, this involves applying inputs to the network for which the output values are known. Then, the error (the difference between the value predicted by the network and the known value) is passed back through the network and used to modify the weights so as to reduce the error. In order to help in deciding when to stop training the network, a number of data points (called the validation or selection set) are normally held back, and the network is deemed to be trained as well as possible when the error for the validation set starts to increase. A further set may also be reserved (the test set) to test the error performance of the network on data that have not been used in any way in the training.

### 2.40.3 Application of Neural Networks to Corrosion

An early published attempt to apply a neural network to a corrosion problem was that of Smets and Bogaerts.<sup>2</sup> They developed a series of neural networks to predict the SCC of type 304 stainless steel in near-neutral solutions as a function of chloride content, oxygen content and temperature. They found that the neural network approach outperformed traditional regression techniques (this should always be the case with a well-fitted network, as it is always possible for the network to model a linear fit). The network used had almost as many weights (35) as the number of examples in the data set used to train it (39). Thus, there may have been a tendency for the network to fit the 'noise' in the data as well as the mean behavior.

Urquidi-Macdonald *et al.*<sup>3</sup> developed a neural network model for predicting the number and depth of pits in heat exchangers. No information was given about the network size (other than that it had two hidden layers) or the number of training points, although there appear to be rather few. Hence, there must be some uncertainty about the reliability of the predictions obtained. On the other hand, the predicted evolution of pit depth and number do appear plausible.

Ben-Hain and Macdonald<sup>4</sup> describe the use of neural network models to predict the influence of various parameters on the acidity of simulated geological brines. The solutions were based on NaCl plus MgCl<sub>2</sub>; the network inputs were the Na<sup>+</sup> and Mg<sup>2+</sup> concentration and the temperature, and the output was the predicted pH value. A relatively large training set was available (101 points, of which 90 were used for training, with the remaining 11 retained as a test set), and a very simple network was used (just two hidden nodes in a single layer), and it is perhaps not surprising that the network achieved a good result. The prediction error was of the same order as the experimental uncertainty.

Silverman and Rosen<sup>5</sup> combined artificial neural networks with an expert system in order to predict the type of corrosion from a polarization curve. Inputs to the networks included the passive current density, the pitting potential and the repassivation potential, while outputs were the risks of crevice, pitting and general corrosion. Two approaches were used: independent networks for each type of corrosion, and a single combined network producing all three outputs. The expert system was used to interpret the outputs produced by the two approaches. This combination of neural network with an expert system 'supervisor' offers interesting possibilities, although in this particular case it seems probable that the available training set (87 examples) was not really adequate to describe the dependence of the type of corrosion on the seven input variables. Hence, a larger training set could have led to neural networks that were sufficient by themselves.

Silverman<sup>6</sup> also applied neural network methods to the prediction of service behavior of polymeric linings from laboratory test data. Inputs to the network were parameters obtained from a short-term solvent-uptake test, while the output was a pass-fail description of service behavior. Taking into account the inherent difficulty of this problem, the results obtained seem promising. For example, the neural network was able to produce a correct prediction for three out of four examples of a lining material that was not included in the training data. Silverman's neural network models have since been adapted for web access.<sup>7</sup>

Ramamurthy *et al.*<sup>8</sup> used a neural network to analyze impedance data for automobile paint finishes subjected to stone impacts. The paper contains very little detail on the data set or the network, and it is difficult to assess the performance of the network. However, the data presented suggest that

the network is too large, and fits the noise in the training data rather than the mean behavior.

Trasatti and Mazza<sup>9</sup> developed a neural network for the prediction of crevice corrosion behavior of stainless steels. The network was trained from long-term laboratory and field tests. Seventeen input variables were used with one hidden layer of five nodes. Six hundred training examples were available; 450 of these were used for training and the remaining 150 as a test set. The performance of the network was reasonably good, but the very large number of input variables might be expected to present difficulties in training with a relatively small data set. A 17-dimensional hypercube has 2<sup>17</sup> (about 130 000) 'corners,' so the data space is inevitably very sparsely populated.

Nesic and Vrhovac<sup>10</sup> have studied the prediction of corrosion of steel in CO<sub>2</sub>-containing solutions. The prediction ability was found to be significantly better than conventional models, although there are some questions about the number of coefficients used in the network.

Neural network methods have been used to fit the corrosion rate of austenitic stainless steels in sulfuric acid using the data set described earlier.<sup>11</sup>

Since the paper on which this chapter is based was published in 1999, there have been about 100 articles published on the application of neural network methods to corrosion. The subject areas that have been covered include:

- atmospheric corrosion<sup>12-23</sup>
- corrosion and degradation of steel-reinforced concrete<sup>24-35</sup>
- marine corrosion<sup>36-45</sup>
- erosion-corrosion<sup>46</sup>
- organic coatings<sup>47-51</sup>
- corrosion fatigue<sup>52-56</sup>
- pipeline and oilfield corrosion<sup>37,39,57-63</sup>
- alloy optimization<sup>64</sup>
- damage assessment<sup>65</sup>
- pitting corrosion<sup>66-68</sup>
- general corrosion<sup>69-73</sup>
- interpretation or simulation of polarization curves<sup>74-77</sup>
- corrosion in aircraft<sup>78-85</sup>
- refinery corrosion<sup>86-88</sup>
- corrosion monitoring and inspection<sup>89-91</sup>
- stray current corrosion<sup>92</sup>
- metallic coatings<sup>93</sup>
- CO<sub>2</sub> corrosion<sup>94-96</sup>
- cathodic protection anode performance<sup>97</sup>
- oxidation in high temperature water and steam<sup>98-100</sup>

- stress corrosion cracking<sup>63,101</sup>
- identification of corrosion type<sup>102–104</sup>
- high temperature oxidation and corrosion<sup>105,106</sup>
- hydrogen effects.<sup>107</sup>

One of the difficulties of working with prediction in multiple dimensions is that of representing the results. All that can be done on two-dimensional paper is to plot representative sections through the data, either as simple two-dimensional plots, or as pseudo-three-dimensional plots. The only complete way of reporting the results of a neural network fit is to present the coefficients of the individual nodes, together with a description of the network. Clearly, this is not a very helpful representation for the casual reader. The alternative representation would be a computer program that implements the neural network, and thereby provides means of interrogating the network. However, even this is not very effective in representing the essence of the neural network model in a way that provides a general view of the relationships involved. We do not, as yet, have a good method of achieving this.

#### 2.40.4 Variability of Corrosion Data

While it is useful to represent the expected corrosion rate as a function of the controlling parameters, this is not a complete representation of the corrosion behavior. Corrosion is inherently variable; as well as knowing the average corrosion rate, it is also important to know the variability of the behavior, as it is the

extreme behavior that will typically cause a corrosion failure, rather than the average. Methods are currently being developed to derive the variability of the training data. A simple approach illustrated in **Figure 3** is to assume that the deviation of the training data points from the fitted neural network is an indication of the inherent variance of the training data. Then, a second network can be fitted to this variance information to derive a model of the variance of the corrosion rate as a function of the controlling variables. While this is a relatively transparent way of obtaining an estimate of the variance, there may be better ways of achieving this and this is the subject of current research. One thing that is clear is that a larger data set is required to obtain a good prediction of the variance as a function of the input variables, since the training data for variance are inherently noisy. In the absence of sufficient data points to model the variance as a function of the input variables, the best that can be done to overcome this problem is to estimate the average behavior as the mean-square residual, although it may be better to use the residual as a proportion of the mean at each point (i.e., to assume that the coefficient of variation is constant over the problem domain).

#### 2.40.5 Confidence in Fitted Function

In general, one limitation of fitting techniques is the way in which they isolate the user from the original

**Figure 3** Estimation of variance.

**Figure 4** Regions of low confidence in a neural network prediction: (a) More reliable interpolation? and (b) Less reliable interpolation?

data. It is apparent from [Figure 4](#) that any attempt to predict the corrosion rate in the central region is unlikely to be reliable. However, when the corrosion rate is produced as an output from a neural network or any other fitting function, this limitation is lost, and a naive user may assume that the prediction is as reliable as a prediction from regions with a high density of training data. Indeed, the imagined infallibility of computer programs may lead users to place greater faith in the prediction of the neural network.

Consequently, it is important to provide some indication of the confidence that can be placed in the prediction of the network. If the original training data are available, the 'distance' from the nearest training points can be determined, and this can be used as an indicator of confidence. Alternatively, an additional network can be trained on the local density of points. This may not be an entirely accurate estimate. [Figure 4](#) shows cases with equivalent distance between the training points, but with a somewhat

different perceived confidence in the interpolation or extrapolation. The continuous, consistent slope in **Figure 4(a)** gives a strong expectation that the line will continue between the two data regions. On the other hand, the inconsistent slopes in **Figure 4(b)** lead to uncertainty about the intervening region and hence a much lower confidence than in **Figure 4(a)**. These perceptions may, of course, be misleading, but this just underscores the difficulty of estimating the confidence that can be placed in the prediction of a neural network (or any other interpolation method). With a simple two-dimensional system such as that shown in **Figure 4**, it is relatively easy to see the implications of the interpolation process. However, in six-dimensional space it is much more difficult to visualize the relationship between the training data points and the interpolated result, and consequently it is important to develop a quantitative estimate of the confidence that can be placed in the prediction. Again, this is the basis of ongoing research.

### 2.40.6 Inconsistent Data Sets

As several groups have shown, neural network techniques can be very effective for modeling corrosion behavior. However, these methods require consistent data sets. To look at another example, work on pitting corrosion of austenitic stainless steels has used a number of measurement techniques, including the measurement of pitting potential, the ferric chloride exposure test (ASTM G 48) for critical pitting temperature (CPT) or various electrochemical methods for the measurement of CPT. If we are interested in the effect of steel composition, we can use neural network methods to fit the individual types of measurement (this has been done for the particular groups mentioned above<sup>108</sup>). This provides useful information, but fails to take full advantage of the ‘relatedness’ of the three data sets. In this case, it is apparent that we should be able to get better estimates if we could take account of all the data in the related data sets. We do not, as yet, have ways of doing this.

A similar problem is concerned with the relatively poor quality of many corrosion results. In this context, poor quality may indicate one or more of many limitations in the recorded data:

- Errors in the data arising from poor experiment design, faulty equipment or miscalculation. It is hoped such errors are rare.

- Failure to measure, control or report significant variables. For any work concerned with the effect of alloy composition on corrosion behavior, the reporting of nominal, rather than actual, compositions introduces a significant uncertainty, and degrades the value of the result. Similarly, failure to report or control environmental variables such as flow rate, oxygen concentration or temperature restrict the value of the data recorded.
- The summarization of data, for example, by plotting lines without the data points on which the line is based, seriously limits the use of such data for further analysis, and, in particular, tends to lose information about the variability and reliability of the data. It is less of a problem to report mean and standard deviation (e.g., as ‘error bars’) for measured data, as examples of the original data can be recreated by Monte Carlo methods. However, it is still better to know the exact data.

### 2.40.7 Training Data Requirements

In the introduction to prior work, we have placed significant emphasis on the number of training points, the number of input variables and the number of weights in the network. The significance of these values has often been misunderstood in the application of neural methods to corrosion problems. Even the neural network literature is somewhat unclear about what is acceptable for a good performance from a network. It may therefore be useful to examine this in a little more detail, although it should be appreciated that there is only a limited theoretical basis for this discussion.

We can consider the basic objective of the training of the neural network to be the accurate modeling of the expected value of the outer parameters (in the statistical sense of most likely value) over the relevant regions of the problem domain. By the problem domain we mean the multidimensional space defined by all the input parameters, with the ‘relevant region’ being the range of input parameters for which we want the output to be valid. Note that in many problems there may be strong correlation between input parameters, such that only a limited region of the problem domain is significant. In effect, this means that the effective dimensionality of the problem is less than the number of input variables would imply. This has important consequences for the number of training points that will be required, but the general analysis of this problem requires further work. We shall therefore consider only the case

where there is little correlation between the input variables, other than through possible clustering.

In general, an  $M$ -dimensional hypercube has  $2^M$  'corners.' A reasonable objective of a training data set would be to have a point on each corner of the hypercube. In experimental terms, this corresponds to taking two values of each variable and performing experiments for every combination of the two values. Thus, for one input variable this corresponds to taking one measurement at each of the maximum and minimum values of the input parameter and drawing a straight line between them. On this basis, two points might be rather low, and 3, 4, or more points might be better. However, the application of this approach over multiple dimensions leads to rapidly escalating requirements for the number of training points. If we cover all the possible combinations of  $N$  values for each  $M$  variable, we require  $N^M$  measurements. For example, for the relatively modest case of six input parameters we need 64 729 and 4096 measurements to provide 2, 3, and 4 points along each axis.

Unfortunately, corrosion data are generally expensive to produce, and large corrosion data sets with sufficient consistency to be suitable for training neural networks are rare. It is therefore generally the case that neural networks for corrosion data reduction must be trained on fewer points than is ideal. This leads to questions about acceptable network architectures, dimensions and training methods. This is a complex subject, and one that has not been fully defined.

From a simple information theory viewpoint, each weight used in the network provides one degree of freedom for the function produced by the network, and there should be at least one training point for each degree of freedom. If the training data are noisy, more training data (or fewer weights) will be required, otherwise the network will model the noise rather than the average behavior. On this basis, a good rule of thumb would appear to be that there should be at least twice as many training points as weights in the network. However, this rule is frequently broken, apparently without ill-effects, and it appears that over-large networks may produce acceptable behavior if the training method used is not too aggressive. Furthermore, methods have been proposed that allow the less important connections to be 'pruned' (their weights set at or near zero), thereby permitting a more complex network to be used while still retaining a good generalization ability. This is another area that merits further study. Until these questions have been clarified, we suggest that the

guideline of two training points for every weight<sup>109</sup> should be taken as the ideal.

Recently, Liu *et al.*<sup>52</sup> have used Newton interpolation to create artificial data points between existing points in order to increase the number of training points and the density of points in the problem domain. However, at first sight, this is effectively training the network to perform Newton interpolation, and it is questionable whether it offers real advantages.

## 2.40.8 A Particular Example

To conclude this introduction to the use of neural networks for the handling of corrosion data, we shall show the results obtained for a 'purpose-built' experimental data set that examined the pitting potential for type 304 austenitic stainless steel as a function of solution composition and temperature. The input variables were the concentrations of  $\text{Cl}^-$ ,  $\text{I}^-$ ,  $\text{Br}^-$ ,  $\text{F}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{CO}_3^{2-}$ ,  $\text{OH}^-$ ,  $\text{NO}_3^-$ , and  $\text{S}_2\text{O}_3^{2-}$  and the temperature of the solution, and the output was the pitting potential (the latter term being interpreted rather imprecisely as that potential at which the anodic current started to increase rapidly – this may therefore correspond to transpassive corrosion or oxygen evolution).

The data set consisted of 200 measurements distributed at random through the 10-dimensional problem domain. Various network architectures and training methods were examined, but for the results reported here, 2/3 of the data were used for training, with the remaining 1/3 being used as a validation set to determine when to terminate training. A very simple network was used with only four nodes in a single hidden layer. This produced a network with a total of 75 weights, just over half the number of training points.

As noted previously, it is very difficult to represent or test the properties of a 10-dimensional function. The best that we have been able to do so far is to compare the predictions for simple situations, in which only one variable is changed with the corresponding experimental data. The results of this exercise are shown in **Figures 5–10**, in which the network predictions are compared with the experimental results of Man and Gabe<sup>110</sup> and with data measured using the same material and test method as were used to produce the training data (these results were not included in the training or validation data). In general, it can be seen that the network predictions are reasonable, but not

**Figure 5** Effect of chloride concentration on pitting potential.

**Figure 6** Effect of sulfate on pitting potential in 3% NaCl solution.

outstanding. The failure to provide completely accurate predictions is understandable, and demonstrates the fundamental problems of this approach to corrosion prediction. The training data set is small by comparison to the size of the problem (the 10-dimensional

hypercube has 1024 corners, compared to our training data set of only 133 points). This, then, requires the use of a small network in order to avoid the possibility of memorizing the data, rather than generalizing. The conditions used for plotting, with 7 or 8 of the 9

**Figure 7** Effect of carbonate concentration on pitting potential in 3% NaCl solution.

**Figure 8** Effect of nitrate concentration on pitting potential in 3% NaCl solution.

concentrations set to 0 (modeled as  $10^{-6}$  M to accommodate the log scaling used for concentration) lie right at the 'edges' of the problem domain, implying that an element of extrapolation is inevitably occurring. When these difficulties are taken into account, it seems reasonable to suggest that the neural network model performs remarkably well.

Owing to the rather small training set relative to the size of the problem, it is not realistic, at least with

our current methods, to try to extract the variance information from the network. However, the residual error (that part of the training data that is not accounted for by the network) is of the same order (around 100 mV) as the standard deviation found when repeating experiments for the same conditions, which suggests that the network is modeling the mean behavior reasonably well, and that the residual errors are largely a result of real variability in the

**Figure 9** Effect of hydroxide concentration on pitting potential in 3% NaCl solution.

**Figure 10** Effect of temperature on pitting potential in 3% NaCl solution.

measured value. As the training data have been deliberately distributed throughout the problem domain in a relatively uniform way, there is no point in assessing the confidence that can be attributed to the prediction of the network.

### 2.40.9 Conclusions

- Artificial neural networks have generally been claimed to be successful in modeling various types of corrosion behavior. However, it is difficult to evaluate the quality of the model that is provided by a neural network with many input variables, and many studies have only validated the performance of the neural network to a limited extent.
- There is a need to model the variability in the corrosion behavior as well as the mean behavior. This can be done, but requires rather larger training data sets than the modeling of the mean.
- There is a need to provide an indication of the confidence that can be placed in the prediction of a neural network. This requires further work towards developing the necessary techniques.

### Symbols

***a*** Depth of a corrosion event  
***a<sub>max</sub>*** Deepest corrosion event  
***a<sub>cr</sub>*** Critical depth  
***b*** Bulk  
***b*** Inverse Tafel constant  
***C<sub>k</sub>*** Concentration of species *k*  
***d*** Thickness of the wall  
 ***$\bar{D}$***  Average diffusivity of breakdown sites  
***D<sub>k</sub>*** Diffusion coefficient of species *k*  
***D<sub>t</sub>*** Turbulent diffusion coefficient  
***E*** Potential  
***E<sub>corr</sub>*** Corrosion potential

$E_{\text{crit}}$  Critical potential for localized corrosion  
 $E_{\text{rp}}$  Repassivation potential  
 $E_0$  Equilibrium potential  
 $F$  Faraday's constant  
 $F_k$  Integral damage function for corrosion event,  $k$   
 $f_k$  Differential damage function for corrosion event,  $k$   
 $G^{\text{ex}}$  Excess Gibbs energy  
 $I$  Current density  
 $I_{\text{ss}}$  Steady-state passive current density  
 $i_a$  Anodic current density  
 $i_c$  Cathodic current density  
 $i_{\text{corr}}$  Corrosion current density  
 $i_p$  Passive current density  
 $i_0$  Exchange current density  
 $i_{\text{corr}}^0$  Current density on the bare surface  
 $i^*$  Current density calculated in the absence of a potential drop in the cell  
 $J_{\text{ca}}$  Flux of cation vacancies  
 $J_{\text{m}}$  Annihilation flux of metal vacancies  
 $j_k$  Flux of species  $k$   
 $K$  Constant in [eqn \[70\]](#)  
 $k_i$  Reaction rate for  $i$ th reaction  
 $K$  Equilibrium constant  
 $K_I$  Stress intensity factor  
 $K_{\text{ISCC}}$  Critical stress intensity factor  
 $k_m$  Rate of chemical reaction  $m$   
 $K_v$  Electrochemical equivalent volume  
 $L$  Thickness of barrier layer  
 $L_{\text{ss}}$  State thickness of barrier layer  
 $m$  Constant in [eqn \[70\]](#)  
 $N$  Total number of nucleated stable pits  
 $n_k$  Rate of nucleation of defect  $k$   
 $Q$  Quasipotential  
 $P_f$  Probability of failure  
 $R$  Gas constant  
 $R_k$  Rate of production or depletion of species  $k$   
 $Re$  Reynolds number  
 $s$  Surface  
 $S$  Surface area  
 $Sc$  Schmidt number  
 $T$  Temperature  
 $t$  Time  
 $t_s$  Service time  
 $t_{\text{in}}$  Incubation time  
 $t_{\text{pr}}$  Propagation time  
 $u$  Central parameter  
 $u_i$  Mobility of species  $i$   
 $U_0$  Open circuit potential  
 $v$  Hydrodynamic velocity

$V_k$  Rate of propagation of corrosion defect  $k$   
 $V_0$  Initial pit propagation rate  
 $\bar{V}_0$  Mean initial pit propagation rate  
 $V_{\text{app}}$  Applied voltage  
 $V_c$  Critical voltage  
 $V_m$  Electrode potential  
 $X_i$  Internal independent variable  
 $X_m$  Average depth of the largest pit  
 $x$  Depth of penetration  
 $x_0$  Characteristic depth  
 $Y_i$  External independent variable  
 $z$  Direction perpendicular to the surface  
 $z_k$  Charge of species  $k$   
 $\alpha$  (1) Anodic transfer coefficient, (2) scale parameter, (3) polarizability of the barrier layer/solution (outer layer) interface  
 $\beta$  (1) Tafel coefficient using natural logarithms, (2) dispersion in Laplace's distribution  
 $\Delta G_s^0$  Standard Gibbs energy change for the chloride absorption reaction  
 $\Delta G_s^0$  Change of Gibbs energy for the Schottky-pair reaction  
 $\Delta K$  Stress intensity factor range  
 $\epsilon$  (1) Dielectric permittivity, (2) electric field strength within the barrier layer  
 $\dot{\epsilon}_{\text{ct}}$  Crack tip strain rate  
 $\epsilon_f$  Fracture strain  
 $\gamma$  Delay repassivation constant  
 $\gamma_k$  Activity coefficient of species  $k$   
 $\Gamma$  Ratio of the bare surface of the crack tip to the total geometric surface  
 $\eta$  Dynamic viscosity  
 $\Delta K_{\text{th}}$  Threshold stress intensity factor range  
 $\kappa$  Conductivity  
 $\lambda$  (1) Constant in [eqn \[83\]](#), (2) function defined by [eqn \[97\]](#)  
 $\mu_k$  Chemical potential of species  $k$   
 $\nu$  Kinematic viscosity  
 $\nu_k$  Stoichiometric coefficient of species  $k$   
 $\rho$  Density  
 $\xi$  Critical areal concentration of vacancies  
 $\zeta$  Survival probability  
 $\sigma$  Standard deviation  
 $\tau$  Dissolution time  
 $\Phi$  Cumulative distribution function  
 $\varphi$  Electrical potential  
 $\Psi$  Extreme value distribution  
 $\psi$  Laplace's distribution function  
 $\Omega$  Mole volume of the barrier layer per cation

### 2.39.1 Introduction

As our industrial and infrastructure systems (refineries, power plants, pipelines, etc.) age, there is a considerable economic incentive to avoid unscheduled outages and to extend operation beyond the design lifetime. The avoidance of unscheduled outages is of particular interest, because the failure of even a minor component can result in the complete shutdown of a facility. For example, the unscheduled shutdown of a 1000 MWe nuclear power plant due to the failure of a valve may cost the operator between \$1 million and \$3 million per day, depending upon the cost of replacement power and other factors. However, if component failures could be accurately predicted, maintenance could be performed during scheduled outages, the cost of which has already been built into the price of the product, thereby minimizing the economic impact of the failure. With regard to life extension, the successful extension of operation beyond the design life translates into enhanced profits and the avoidance of costly licensing and environmental impact assessments associated with the development and construction of a new facility. However, in this case as well, the key to successful operation is the ability to avoid unscheduled downtime and hence maintain continuity of production. However, eventually, the frequency and severity of unscheduled outages render continued operation uneconomic and, at that point, replacement of the facility becomes necessary.

Corrosion is a major cause of component failure, and hence the occurrence of unscheduled downtime, in complex industrial systems. In particular, the various forms of localized corrosion, including pitting corrosion, crevice corrosion, stress corrosion cracking (SCC), and corrosion fatigue (to name the common forms), are particularly deleterious, because they frequently occur without any outward sign of accumulating damage and because they often result in sudden and catastrophic failures. Thus, the development of effective general and especially localized corrosion damage prediction technologies is essential for the successful avoidance of unscheduled downtime and for the successful implementation of life extension strategies.

There are two main approaches for predicting corrosion damage – empiricism and determinism. ('Determinism' is used here in the physics sense to describe a model whose predictions are constrained to the 'physically viable' realm by the natural laws. The term 'determinism' is often used in engineering disciplines to indicate a model that provides a definite output in response to a definite input.) Empiricism is the philosophy that everything we

can ever know must have been experienced. On the other hand, determinism is the philosophy that we may predict the future from the past via the natural laws. Within these two classes, there exist numerous subclasses. For example, within the empirical class, there are functional models, in which (discrete) data are represented by continuous mathematical functions; statistical models; and artificial neural networks, to name a few. Within the broad class of 'deterministic' models, there can exist 'definite' models that yield a single output for a given set of input values; and probabilistic models, in which the inputs are distributed resulting in a distributed output from which the probability of an event occurring can be estimated.

It must be noted that, up to now, the prediction of corrosion damage has been largely based on the application of empirical models and only in the past decade, or so, have deterministic models been developed.

It is important to note that there are particular difficulties in using purely empirical models for predicting corrosion damage in real industrial systems, caused by the following factors: (i) Empirical models are generally expensive, because of the need for large databases covering many independent variables for calibration. Complex industrial systems are unique, even when they are of the same design, because they endure different operating conditions and histories. Thus, for example, an airplane that has been operating in a hot, humid environment might require more inspection and maintenance than an identical aircraft based in a desert environment. (ii) Failures are rare events. Accordingly, it is generally impossible to develop an effective database for model calibration based on the failure statistic of any given system. (iii) Empirical models also fail to capture the mechanism of failure.

Of course, deterministic models also pose many challenges. The most important of these are as follows: (i) Corrosion is an extremely complex phenomenon that depends on a multitude of factors, including the chemistry of the environment, metallurgy, and thermomechanical history of the corroding metal, hydrodynamics of multiphase flow, geometry, stress, temperature, pressure, and so on; (ii) the lack of information on kinetic parameters of the corroding system; and (iii) the need to define the corrosion evolutionary path (CEP). Because any model that is developed to describe the damaging process, and on which the deterministic prediction of damage is based, is only a figment of our imagination, and is based upon inputs from imperfect senses that are interpreted through an imperfect intellect, it is clear

that a working deterministic model can yield only an approximate description of a real system. Accordingly, pure ‘determinism’ is an ideal concept that is probably never achieved in reality, and the complementary, use of deterministic and empirical model provides the most effective method for predicting corrosion damage. Nevertheless, through the application of the ‘scientific method,’ in which a model is continually revised as it is cyclically tested against new observations, many deterministic models evolve toward providing accurate descriptions of real systems.

At this point, it is necessary to contrast the philosophical bases of ‘mechanistic models’ and ‘deterministic models,’ because great confusion exists in the literature on this issue. A mechanistic model is based upon a realistic mechanism for the process that is underpinned by a valid theory that, ideally, accounts for all of the observed properties. There is no requirement that the output must be constrained by the natural laws, as is the case for a deterministic model. Frequently, it is found that the values of unknown parameters are simply determined by calibration, whereas, in a deterministic model those same parameter values would be determined by the constraints. Given sufficient complexity and enough unknown parameters, a mechanistic model can be made to fit any data set imaginable and then yield predictions that are frequently at odds with reality. This cannot happen in the case of a deterministic model because the constraints, which are expressions of scientific generality (i.e., the ‘natural laws’), limit the predictions to a realm that is consistent with the constraints themselves (i.e., to physical ‘reality’).

The need to define the CEP has been explained above. The CEP is defined as the path taken by the system in terms of those independent variables that have a significant impact on the rate of damage accumulation in transitioning from the present state to the future state. This path must be continuous and is required for both deterministic and empirical damage prediction models. Examples of defining the CEP are given later in this chapter, when we discuss the prediction of damage in practical systems.

In this article, we review recent advances in the development of some deterministic models for predicting corrosion damage (the review of some empirical models, including statistical models and artificial neural networks can be found in other articles in this volume). This subject is much too broad for justice to be done in a single chapter of the current length, but, by limiting the scope, the authors wish to illustrate the essential elements of theory and deterministic

model-building and to demonstrate how the models can make useful predictions. The cases discussed have been chosen to address practical problems in current science and engineering, and, where possible, applications of the models to real engineering problems have been selected.

## 2.39.2 Definition of Corrosion Damage

As is well known, corrosion damage can be classified into two categories: uniform (general) corrosion and localized corrosion, and the quantitative description of these two cases are quite different. In this review, principal attention will be devoted to the case of localized corrosion. However, it must be noted that, in the general case, it is impossible to describe the propagation of localized corrosion damage without having reliable deterministic models for general corrosion, because the latter models yield the most important value for predicting the rate of localized corrosion; namely, the corrosion potential,  $E_{\text{corr}}$ .

In the case of general corrosion, it is natural to define corrosion damage at a given point on a metal surface as being the thickness of the metal layer that has corroded,  $a$ . This definition means that we can predict general corrosion damage if we can calculate  $a$  as a function of time and of the independent variables controlling the damaging process, that is,  $a$  is predicted in the form:

$$a = a(t, X_i, Y_i) \quad [1]$$

Here,  $X_i$  and  $Y_i$  are internal and external independent variables, respectively, that determine the damage propagation rate. Examples of internal variables are grain size and orientation, texture, electrochemical kinetic parameters, and other microstructural properties. The external variables include loading and environmental conditions.

Even the term ‘uniform corrosion’ shows that, usually, the corroding layer thickness,  $a$ , depends slightly on the coordinates on the metal surface, if internal and external variables can be considered to be approximately constant for different parts of the system. In other words, it is assumed that, for a given set of conditions, uniform corrosion damage can be characterized for a given time and for given environmental conditions by a single value – average thickness of the corroded layer. Accordingly, for the case of general corrosion, the service life of the system,  $t_s$ , can be defined as the duration before the corroding

layer thickness achieves some average critical thickness,  $a_{cr}$ , (or reaches some minimum allowed value). Usually, the uniform corrosion data are analyzed by using the normal distribution. It is also assumed that the standard deviation of the thickness of the corroded layer,  $\sigma$ , can be estimated by using eqn [1], if the standard deviations of values  $X_i$  and  $Y_i$  are known by using, for example, the standard method for calculating the propagation of error.

In the case of localized corrosion, the situation becomes more complicated. Generally speaking, the accumulation of localized corrosion damage in a system is completely defined if we know how many pits or other corrosion events (per square centimeter) have depths between  $x$  and  $x + dx$  for a given observation time,  $t$ , at a given location on the metal surface. We will denote this quantity as  $f_k(x, t)dx$  where  $f_k(x, t)$  is the so-called differential damage function.<sup>1</sup> Here, the index  $k$  denotes different types of localized defects, such as active and passive pits, cracks, crevices, and so on.

However, in the overwhelming majority of practical cases, such complete information is not required to effectively predict the failure time due to the penetration of the deepest event. Thus, very often, it is sufficient to obtain information about only the deepest corrosion event (pit, crack), because failure in the system commonly occurs when the depth of the deepest corrosion event  $a_{max}$  exceeds some critical value,  $a_{cr}$ . Usually,  $a_{cr}$  is the thickness of the wall of a pipe, for example, or the depth of a pit transitioning into an unstable crack. With regard to the first case, in order to describe the damage, we can use an equation of the previous form, that is,

$$a_{max} = a_{max}(t, X_i, Y_i) \quad [2]$$

Accordingly, the service life of the system,  $t_s$  (that is sometimes denoted as being the time to failure,  $t_f$ ) can be expressed as the sum of incubation period,  $t_{in}$ , and propagation period,  $t_{pr}$ , in order for the defect to attain a critical depth:

$$t_s = t_{in} + t_{pr} \quad [3]$$

The period of propagation,  $t_{pr}$ , can be divided into periods corresponding to different forms of propagating of the corrosion defect; for example, in the form of pit,  $t_{pit}$ , or in the form of crack,  $t_{cr}$ , if the crack nucleates from the pit. In turn, for example,  $t_{cr}$  can be subdivided into the period  $t_{cr,c}$  (the time required for the surface crack to grow into a through crack) and  $t_{cr,g}$  (the time for a through crack to grow to a prescribed critical length), and so on.

It is important to understand that even if relation [2] can be obtained, its applicability would be questionable. The problem is that eqn [2] yields a single number for  $a_{max}$  for a given value for  $t$  and for other parameters of the system. However, in the general case, it is impossible to describe available experimental data by a single number. Thus, Table 1 shows typical data for the depths of the deepest pits experimentally measured<sup>2</sup> on 20 sampled areas of  $300 \times 300$  mm on the bottom outer surface near the periphery of a circular tank made of SS41 carbon steel, storing heavy petroleum, after 7 years of service; all of the pit depths not smaller than 0.5 mm were recorded, and the maximum pit depth in each sampled area was noted. The experimental data were taken from Harlow and Wei.<sup>3-7</sup>

We see that the difference between the observed values is greater than 280%. It is clear that, in the general case, prediction of corrosion damage can be done only in probabilistic terms. Apparently, the best form of predicting localized corrosion damage would be prediction of the probability of failure,  $P_f$ :

$$P_f = P_f(a_{cr}, t, X_i, Y_i, S) \quad [3]$$

that is, the probability that at least one corrosion event of any form (pit, stress corrosion crack, fatigue crack) reaches some critical depth,  $a_{cr}$ , at a given observation time,  $t$ , for any given set of environmental conditions. It is essential that  $P_f$  must be a function of the total area of the system, because the larger the area of the system, the larger will be the number of corrosion events and hence the greater the probability that a deeper event will exist. Accordingly,  $P_f$  must increase with area.

**Table 1** Maximum pit depth distribution,  $a_{max,i}$  (in ascending order) for oil storage tank

	<i>i</i>								
	12	13	14	15	16	17	18	19	20
$a_{max,i}$ (mm)	0.65	0.71	0.75	0.84	0.90	1.07	1.18	1.25	1.82

Index  $i$  numerates samples. Samples with  $i < 12$  have maximum pit depth of  $< 0.5$  mm.

Let us consider possible ways for theoretically estimating this probability. The most intensive work that has been reported on predicting corrosion (in aluminum alloys) is that of Harlow and Wei,<sup>3-7</sup> whose important achievement has been to insert into prediction technology the realization that an analytical description (not necessarily a deterministic description) of the accumulation of damage is possible. Their approach is as follows: It is assumed that a pit is nucleated at an initial moment,  $t = 0$ , with an initial depth of  $a_0$ , and that the depth increases with increasing observation time,  $t$ . At some critical depth,  $a_{cr}$ , the pit transitions into a crack. By using mechanically-based models for calculating pit or crack propagation rates, an analytical expression for the depth of the corrosion event,  $a$  (in the form of a pit or crack), as a function of time is found in analytical form, as described by eqn [1]. All variables  $X_i$  and  $Y_i$  (where only temperature has been included in the environmental variables) are subdivided into two parts: deterministic parameters (in the engineering sense, i.e., parameters with fixed values) and random parameters, with the latter obeying, for example, the Weibull distribution. Subsequently, eqn [1], together with the change-of-variable theorem, or standard Monte Carlo technique, may be used to estimate the probability of failure,  $Pr(a > a_{cr}, t)$ , that is, the probability that the crack length,  $a$ , exceeds the prescribed critical length of the crack,  $a_{cr}$ , at given observation time,  $t$ . The obvious problem with this approach is that it is completely devoid of environmental effects, such as those of potential, pH,  $[Cl^-]$ , and solution conductivity on pit and crack nucleation and growth, even though these effects have been established experimentally and are consistent with field observations. Accordingly, the underlying model for damage propagation fails to explain all of the experimental observations and hence is not viable. The second problem is that, by selecting a single pit, the significant literature demonstrating that pitting, which leads to cracking, is a progressive phenomenon in which new pits nucleate as existing pits grow and die (repassivate), is ignored. Thus, by selecting a particular pit initially, there is no way of knowing, *a priori*, whether that pit will survive to grow to a critical depth and hence, nucleate a crack. Indeed, the approach taken by Harlow and Wei is, in form, very similar to that employed by Liu and Macdonald<sup>8,9</sup> in the early 1990s to describe the failure of low pressure steam turbines, except that the latter study incorporated environmental effects, and the predictions of the component models were

constrained by the appropriate natural laws (including the conservation of charge, recognizing the electrochemical nature of the damaging processes).

The question then arises whether the models of Harlow and Wei, for example, can be generalized by including the influence of environmental parameters, other than temperature, in explicit form. Even if they were able to do so, which, in itself, would require a massive reformulation of the models to incorporate environmental effects, in our opinion, the applicability of their approach would remain highly questionable, because environmental effects cannot be included in an *ad hoc* fashion. In addition, as noted above, the current Harlow and Wei<sup>3-7</sup> models consider only a single event, whereas it is well known that corrosion damage due to pitting, stress corrosion cracking, and corrosion fatigue accumulates progressively (that is, new pits/cracks nucleate while existing pits/cracks grow and die). In other words, it is impossible, in the general case, to attribute corrosion damage to a single corrosion event on the surface in isolation from all other events. Instead, the development of damage must be described in terms of an ensemble of localized corrosion events.

This thesis is confirmed by the following: The probability that any particular pit will repassivate (die) during the service life of a system is generally very high. Thus, let us consider the classical measurements of pit depth distribution versus time performed by Aziz<sup>10</sup> on Alcan aluminum alloy 2S-O in Kingston tap water (Figure 1). This study showed that by the end of 2 months, the bulk of the pits represented by the bell-shaped curve had ceased to grow (i.e., they had 'died') and only the deeper pits continued to propagate. In other words, by the end of two months from the beginning of the corrosive attack (in this particular case), the overwhelming majority of the pits repassivate (die). Accordingly, there is no way of knowing whether the pit selected had the necessary characteristics to grow to the critical length. In the general case, the probability that the depth of the deepest pit will exceed some critical value depends on the number of nucleated, stable pits and on the probability of repassivation. In some extreme cases, the probability that the depth of the deepest pit increases beyond some critical value is vanishingly small,<sup>11</sup> with the result that cracks will not nucleate. Obviously, this is a scenario that can only be described in terms of a large ensemble of events, rather than in terms of a single event.

In addition, the interaction between growing pits must be taken into account. The presence of existing

**Figure 1** Pit depth distributions for Alcan 2S-O aluminum alloy immersed in Kingston water for different periods of time. The increment in pit depth is 100  $\mu\text{m}$ . Reproduced from Aziz, P. M. *Corrosion* **1956**, 12, 35–46.

pits impacts the probability of nucleation of other stable pits within the neighboring region. This phenomenon has been experimentally reported by Macdonald<sup>12</sup> and is explained by the competition of the pits for the available resources on the external surfaces (oxygen reduction) or because the existing pit cathodically protects the neighboring surface and hence inhibits the nucleation of the second pit. The interaction between the ‘hemispheres of influence’ (subtending the external area over which the cathodic reaction occurs) of growing, stable pits can also reduce the propagation rate of each of the pits, simply by reducing the metal potential at the pit bottom. Finally, we also have to take into account the overlapping between growing pits that also influences the shape and propagation rate. All of this shows that any method for estimating the probability of failure on the basis of the propagation of a single corrosion event (pit or crack) cannot be general.

### 2.39.3 Damage Function Analysis

One of the approaches that considers the accumulation of corrosion damage in terms of the evolution of an ensemble of pits and cracks is damage function analysis (DFA).<sup>1,13,14</sup> (The other possible method, that based on the Monte Carlo simulation of movement of ensemble of corrosion events will also be described below). As mentioned above, the differential damage function,  $f_k(x, t)$  yields the complete description of corrosion damage. It is easy to obtain the differential equation for this function. The function  $f_k$  has a dimension of  $\#/(\text{cm}^2 \text{ cm}) = \#/\text{cm}^3$ , analogous to the concentration of particles. Accordingly, it is very convenient to regard each defect as a ‘particle’ that

moves in the  $x$  direction (perpendicular to the surface, with  $x = 0$  being at the metal surface). The coordinate of this particle,  $x$ , coincides with the depth of penetration into the surface. Accordingly,  $f_k$  must obey the law of mass conservation

$$\frac{\partial f_k}{\partial t} + \frac{\partial j_k}{\partial x} = R_k, \quad k = 1, 2, \dots, K \quad [4]$$

where  $j_k$  and  $R_k$  are the flux density and the bulk source (sink) of the ‘particle’  $k$  respectively. Thus, the subscript  $k$  enumerates the corrosion defect (e.g., pit or crack) and  $K$  is the total number of different corrosion defects in the system. By definition,  $R_k(x, t)dxdt$  yields the number of defects  $k$  (per square centimeter) with depths between  $x$  and  $x+dx$  that arise (or disappear) during the period of time between  $t$  and  $t+dt$ , due to transformation (repassivation, in the case of pits).

The system of eqns [4] can be solved with the appropriate boundary and initial conditions.

$$j_k = n_k(t) \quad \text{at } x = 0, t > 0 \quad [5]$$

and

$$f_k = f_{k0}(x) \quad \text{at } x \geq 0, t = 0 \quad [6]$$

where  $f_{k0}(x)$  is the initial distribution of defect  $k$  (usually we can assume that  $f_{k0}(x) = 0$ , i.e., no damage exists at zero time) and  $n_k(t)$  is the nucleation rate of the same defect (i.e.,  $n_k(t)dt$  is the number of stable defects (per square centimeter) that nucleate in the induction time interval between  $t$  and  $t+dt$ ).

Thus, because the defect propagation flux,  $j_k$ , must be nonnegative (the depth of a corrosion event can only increase with time), the following, simplest numerical upwind finite difference scheme can be used for numerically solving eqns [4]–[6].

$$f_{k,m}^{n+1} = f_{k,m}^n - \frac{\Delta t}{\Delta x} (j_{k,m}^n - j_{k,m-1}^n) + R_k^n \Delta t \quad [7]$$

Here, we use the straightforward approach of choosing equally spaced points along both the  $t$ - and  $x$ -axes:  $x_j = x_0 + m\Delta x$ ,  $m = 0, 1, \dots, J$  and  $t_j = t_0 + n\Delta x$ ,  $n = 0, 1, \dots, N$ , and we denote  $f_{k,m}^n = f_k(t_n, x_m)$ . The values  $f_{k,0}^n$  and  $f_{k,m}^0$  are calculated from the boundary and initial conditions [4] and [5]. Of course, it is assumed that we know (i.e., can calculate) fluxes,  $j_k$ , and sources/sinks,  $R_k$ , as functions of the spatial coordinates and time, and, in nonlinear cases, as functions of the unknown values of  $f_k$ .

It is important to note that, sometimes, the equation of continuity is presented in the simplified form<sup>15,16</sup>

$$\frac{\partial f_k}{\partial t} + \frac{\partial [V_k(x)f_k]}{\partial x} = R_k, k = 1, 2, \dots, K \quad [8]$$

This expression implies that the rate of  $k$ th defect,  $V_k$ , depends only on the depth of penetration,  $x$ , and accordingly, for the flux density,  $j_k$ , we have

$$j_k(x, t) = f_k(x, t) V_k(x) \quad [9]$$

In the simplest cases, it is even possible to obtain analytical solutions for the damage functions. As an example, let us consider the case of pitting corrosion under constant external conditions. In this instance, we have two kinds of defects ( $K = 2$ ): active pits with the damage function,  $f_a$ , and passivated pits (i.e., those that have ‘died’ through delayed repassivation) with the damage function,  $f_p$ . Let us assume that the flux density of active pits is described by eqn [8] with  $V_a(x) = V(x)$ . By definition, the flux of passivated pits is zero (i.e., these pits are ‘dead’). It is evident that functions  $R_a$  and  $R_p$  must obey the relation  $R_p = -R_a$  (a pit must be either alive or dead). If, in addition, we assume that the pit repassivation process obeys a first order decay law, the function  $R_a$  has the form

$$R_a(x, t) = -\gamma f_a(x, t) \quad [10]$$

where  $\gamma$  is the delayed repassivation (‘death’) constant (i.e., the rate constant for repassivation of stable pits). In the general case,  $\gamma$  depends on the depth of the pit,  $x$ , and on time,  $t$ , when the external conditions depend on time. However, in this example, we assume that  $\gamma$  is a constant, that is, we suppose that pits repassivate accidentally and that the probability of repassivation does not depend on pit depth. (This is clearly a gross oversimplification, since the probability of delayed repassivation is expected to increase with pit age, but

this does not change the logic of the argument). Accordingly, the system of equations for calculating the DFs has the form

$$\frac{\partial f_a}{\partial t} + \frac{\partial [V(x)f_a]}{\partial x} = -\gamma f_a \quad [11]$$

and

$$\frac{\partial f_p}{\partial t} = \gamma f_a \quad [12]$$

The boundary and initial conditions are given as

$$Vf_a = n(t) \text{ at } x = 0, t > 0 \text{ and } f_a = f_p = 0 \text{ at } t = 0 \quad [13]$$

where  $n(t)$  is the nucleation rate of pits on the surface. Analytical solutions to this system of linear partial first-order differential equations can be obtained by using the characteristic method<sup>17</sup> and have the following form:

$$f_a = \frac{\exp[-\gamma\theta(x)]n[t - \theta(x)]}{V(x)} \text{ and} \quad [14]$$

$$f_p = \frac{\gamma \exp[-\gamma\theta(x)]N[t - \theta(x)]}{V(x)}$$

where

$$\theta_{\text{pit}}(x) = \int_0^x \frac{dx'}{V(x')} \quad [15]$$

is the age of a pit with depth  $x$  and

$$N(t) = \int_0^t n(t')dt' \quad [16]$$

is the number of stable pits (per square centimeter) that nucleate in the time interval between 0 and  $t$ .

In some cases, it is convenient to use the so-called integral damage function

$$F_k(x, t) = \int_x^\infty f_k(x', t)dx' \quad [17]$$

which yields the number (per square centimeter) of corrosion events with depths larger than  $x$  for a given observation time,  $t$ . It is important to note that, experimentally, only the sum of the damage functions for active and passive pits  $f = f_a + f_p$  is determined and in many instances the integral damage function only is measured. Accordingly, it is important for practical reasons to obtain the equation for the integral damage function,  $F = F_a + F_p$ , for the sum of the active and passive pits. Note that, for the considered case, the integral damage function corresponds to the

**Figure 2** Schematic history of the nucleation and propagation of corrosion damage.

number of remaining pits on a surface, as the surface is removed layer by layer in preestablished increments. From eqns [14] and [17], we therefore have

$$F(x, t) = \exp[-\gamma\theta(x)]N[t - \theta(x)] \quad [18]$$

According to the theory outlined above, calculation of the damage functions requires the determination of three independent functions for each kind of corrosion defect,  $k$ : (1) the rate of defect nucleation,  $n_k$ ; (2) the flux density (growth rate) of the defect,  $j_k$ ; and (3) the rate of transition of one kind of defect into another,  $R_k$  (e.g., the transition of an active pit into a passivated pit or the transition of a pit into a crack). In other words, we need to have quantitative models for describing each stage of corrosion damage as indicated in Figure 2. Below, we will discuss the feasibility of calculating each of these three functions. However, as noted above, the detailed deterministic description of any phase of corrosion propagation is impossible without reliable information about the corrosion potential of the system,  $E_{\text{corr}}$ . Accordingly, in the first step, the methods for calculating  $E_{\text{corr}}$  will be considered.

### 2.39.4 Mixed Potential Model

In 1937, Wagner and Traud<sup>18</sup> formulated their mixed potential theory in electrochemistry, in which the

potential adopted by an electrode in contact with an aqueous solution containing both oxidizing and reducing species is determined by a balance of the cathodic (reduction) and anodic (oxidation) partial processes occurring at the surface. If the electrode is inert, the resulting potential is known as the redox potential,  $E_{\text{redox}}$ . On the other hand, if the electrode is electroactive and undergoes electrooxidation (corrosion), thereby contributing to the total partial anodic current, the potential is known as the electrochemical corrosion potential, ECP (or  $E_{\text{corr}}$ ), of the substrate. Thus, if the partial current densities do not depend on the coordinate on the metal surface, the charge conservation condition for the interface may be written as

$$\sum_k i_{a,k} + \sum_m i_{c,m} = 0 \text{ at } E = E_{\text{corr}} \quad [19]$$

where  $i_{a,k}$  and  $i_{c,m}$  are partial anodic and cathodic current densities, corresponding to the  $k$ th anodic and  $m$ th cathodic reaction correspondingly. This simple theory has proved to have a profound impact on how we interpret the corrosion of metals and alloys in a wide variety of systems.

As an example, let us consider one of the first comprehensive applications of the mixed potential theory in corrosion science to an industrial system, namely the calculation of ECP in the coolant circuits of water-cooled nuclear reactors, particularly boiling water reactors (BWRs), using a mixed potential model (MPM).<sup>19,20</sup> In this complex chemical system (the reactor coolant circuit), radiolysis of the coolant water by ionizing radiation ( $\gamma$ -photons and neutrons) produces a myriad of electroactive species, some of which are oxidizing species (e.g.,  $\text{O}_2$ ,  $\text{H}_2\text{O}_2$ ,  $\text{OH}$ ) and others that are reducing species ( $\text{H}_2$ ,  $\text{H}$ ). These species all contribute to the current flow across the interface, but the mixed potential theory predicts that the contribution that any given species can make to the potential is roughly proportional to its concentration. Thus, in BWR primary coolant circuits, the only species of practical importance are  $\text{O}_2$ ,  $\text{H}_2\text{O}_2$ , and  $\text{H}_2$ , since the concentrations of these species are orders of magnitude greater than those of the other radiolytic species. The reactions describing each of the electroactive species are described as redox reactions, which can be written in the general form as

where R and O are reduced and oxidized species, respectively, with the kinetics of the reaction being

described in terms of the generalized Butler–Volmer equation

$$i_{R/O,j} = \frac{e^{b_{a,j}\eta_j} - e^{-b_{c,j}\eta_j}}{\frac{1}{i_{0,j}} + \frac{e^{b_{a,j}\eta_j}}{i_{l,f,j}} - \frac{e^{-b_{c,j}\eta_j}}{i_{l,r,j}}} \quad [21]$$

where  $b_a$  and  $b_c$  are the anodic (oxidation) and cathodic (reduction) inverse Tafel constants,  $i_0$  is the exchange current density,  $i_{l,f}$  and  $i_{l,r}$  are the mass transport limiting current densities, and  $\eta$  is the overpotential that is defined as the difference between the potential and the equilibrium potential for reaction  $j$ . The parameters  $b_a$  and  $b_c$  are normally measured in separate experiments, but in principle can be calculated *ab initio*. The exchange current density,  $i_0$ , is almost always measured directly, as theory is not sufficiently well developed to calculate this quantity from first principles. In addition to the redox partial reactions (oxidation and reduction processes), the anodic oxidation of the substrate also contributes to the total current density. In this case, the point defect model (PDM)<sup>21</sup> (the PDM will be considered in detail in the next section) provides the functional form of the anodic oxidation current density as

$$i_a = A + Be^{CE} \quad [22]$$

where  $A$ ,  $B$ , and  $C$  are constants that depend upon the values of fundamental parameters in the model and upon the properties of the system (e.g., pH). For metals and alloys that form n-type passive films, in which cation interstitials and/or oxygen vacancies are the dominant defects,  $B=0$ , and the anodic oxidation current density is independent of potential, unless there is a change in the oxidation state of the metal ion (cation or interstitial) being ejected from the barrier oxide layer at the barrier layer–solution interface. Systems of this type include iron and carbon steel, the stainless steels, and the chromium-containing, nickel-based alloys, such as Alloys 600 and 22. On the other hand, for metals that form p-type passive films (e.g., nickel),  $A=0$ , and  $B$  and  $C$  are greater than zero. In this case, the passive current density is described by the Tafel equation.

The conservation of charge requires that the sum of the partial current densities at the interface be zero, with this condition being expressed as

$$i_a(E) + \sum_{j=1}^{\mathcal{J}} \frac{e^{b_{a,j}\eta_j} - e^{-b_{c,j}\eta_j}}{\frac{1}{i_{0,j}} + \frac{e^{b_{a,j}\eta_j}}{i_{l,f,j}} - \frac{e^{-b_{c,j}\eta_j}}{i_{l,r,j}}} = 0 \quad [23]$$

where  $\mathcal{J}$  is the total number of redox reactions in the system. Note that in eqn [19], the summation takes place over the anodic and cathodic reactions

separately, whereas in eqn [23], index  $j$  enumerates the redox reactions, each comprising conjugate partial anodic and cathodic partial reactions. Solution of eqn [23] yields the ECP or the corrosion potential,  $E_{\text{corr}}$ . Note that  $\eta_j = E - E_j^e$ , where  $E_j^e$  is the equilibrium potential for the  $j$ th redox reaction. The limiting currents can be written in terms of the mass transfer correlations for the flow geometry and flow regime of interest.<sup>22</sup>

$$i_{l,j} = \pm n_j F A' Re^\lambda Sc^\gamma C_{O/R}^b \quad [24]$$

where  $n_j$  is the number of electrons involved in the reaction,  $A'$  is a constant,  $Re = dV/v$  is Reynolds number,  $d$  is the hydrodynamic diameter of the channel,  $V$  is the flow velocity,  $v = \hat{\eta}/\rho$  is the kinematic viscosity,  $\hat{\eta}$  and  $\rho$  are the dynamic viscosity and the density, respectively, of the medium, and  $C_{O/R}^b$  is the concentration of the reactive species in the bulk environment. The Schmidt number is defined as  $Sc = v/D$ , where  $D$  is the diffusivity of the reacting species. The sign convention is ‘+’ for the forward direction (left to right) of the reaction [20], as written, and ‘−’ for the reverse direction. Mass transfer correlations of the type expressed by eqn [24] are available in the literature for a wide variety of flow geometries and regimes (Selman and Tobias,<sup>22</sup> and citations therein), with the latter corresponding to specific ranges in  $Re$  and  $Sc$ . Once the corrosion potential is known (by solving eqn [23]), the corrosion current density is readily calculated using eqn [22].

As noted above, the MPM has been used extensively to calculate the corrosion potentials of stainless steel components in the coolant circuits of BWRs, and we will use this case to illustrate the power of this model in defining the response of metals and alloys to the properties of the environment in a complex industrial system. The typical measured and calculated ECP data for a cell attached to the recirculation piping of the Liebstadt BWR in Switzerland as a function of the amount of hydrogen added to the feedwater are plotted in Figure 3. This represents a ‘double blind’ comparison in that those who performed the calculations<sup>19,23</sup> did not have access to the data measured on the reactor, and those who measured the ECP on the reactor (Sierra Nuclear) did not have access to the calculated values. As shown, the measured and predicted corrosion potential data are in good agreement, except for the initial point (zero added hydrogen). However, in this case, it was found that the level of agreement could be greatly improved by changing the mass transport parameters (flow velocity, hydrodynamic diameter, etc.).

**Figure 3** Comparison of calculated and measured ECP for the Leibstadt BWR in Switzerland. The ‘measured’ data were acquired in a test cell attached to the recirculation piping. The data employed in the calculation are summarized in Macdonald and Urquidi-Macdonald<sup>19</sup> and Macdonald *et al.*<sup>23</sup> The estimated accuracies of the calculated and measured data are indicated in the box in the figure.

Since these parameters are poorly characterized for an autoclave at very low flow rates, the disagreement in the absence of added hydrogen is of little consequence.

The accuracy of any MPM model for predicting  $E_{\text{corr}}$  and the rate of uniform corrosion depends on the accuracy of modeling of the rates of particular electrochemical reactions along with the completeness of the set of reactions included in the summation in eqn [19]. A detailed review of different models for the kinetics of corrosion can be found in the corresponding chapter of this book **Chapter 2.38, Modeling of Aqueous Corrosion**. Here we would only like to mention that already existing commercial software yields reliable prediction of the corrosion potential and, correspondingly, the rate of uniform corrosion under relatively complicated conditions, including the influence of adsorption, active–passive transition effects, scaling, transport in porous media, and so on.

Thus, the models of Anderko *et al.*<sup>24–26</sup> and those of others<sup>8,9,19–21,23</sup> have been developed for simulating the rates of general corrosion of selected metals (including carbon steels, stainless steels, aluminum, and nickel-based alloys) in aqueous solutions. The model consists of thermophysical and electrochemical modules. The thermophysical module is used to calculate the speciation of aqueous solutions and to obtain concentrations, activities, and the transport properties of individual species. The electrochemical module simulates partial oxidation and reduction processes on the surface of the metal. It is capable of reproducing the active–passive transition and the

effect of solution species on passivity. The model has been implemented in a program that can be used to simulate the effects of various conditions, such as temperature, pressure, pH, component concentrations, and flow velocity on the corrosion potential and corrosion rate. The model clearly demonstrates the influence of inhibitors on corrosion rate. Good agreement with experimental data has been obtained.

Other comprehensive models have been developed for describing general corrosion under specific conditions. Thus, Nordsveen *et al.*<sup>27</sup> developed a mechanistic model of uniform carbon dioxide (CO<sub>2</sub>) corrosion that takes into account such phenomena as diffusion of species between the metal surface and the bulk including diffusion through porous surface films, migration due to the establishment of potential gradients, and the existence of homogenous chemical reactions, including the precipitation of surface films. Nešić *et al.*<sup>28</sup> developed a comprehensive model for calculating internal uniform corrosion rates under multiphase flow conditions in mild steel pipelines.

However, it is important to note that, in the general case, for calculating ECP and uniform corrosion rate, where extensive localized corrosion may exist on a surface, thereby imparting significant nonuniformity in the current densities, we have to use, instead of eqn [19], the following equation.

$$\int_S \sum_m i_{a,m} dS + \int_S \sum_k i_{c,k} dS = 0 \quad \text{at } E = E_{\text{corr}} \quad [25]$$

It is evident that eqn [25] reduces to eqn [19] when we can assume that the partial current densities do not depend on the coordinates (location) on the metal surface, or if we can neglect any such dependencies. Thus, let us consider the case of pitting corrosion. Of course, the anodic current density inside pits can exceed the passive corrosion current density by several orders of magnitude. However, if the area of the active dissolution (area of pit surfaces) is much smaller than the total area of the metal surface (active corrosion current is much smaller than the passive corrosion current), it may be possible to use eqn [19] instead of eqn [25]; otherwise, such a simplification would be incorrect.

Experiments show that, often, both possibilities can be realized in an industrial system.<sup>29,30</sup> Thus, in the case of the corrosion of Alloy 20Kh13 (the Russian analog of Type 403 SS) in NaCl solutions, the corrosion potential is observed to decrease with time.<sup>30</sup> This reduction occurs due to the intensive growth of corrosion pits, because the total cathodic partial current has

to increase in order to compensate the increasing total partial anodic current, to conserve charge in the system. At some point, this growth stops due to the transport limitation for the cathodic reactant (oxygen), that is, the system is now limited by the lack of cathodic resources to support the ever-increasing corrosion current. On the other hand, such reduction is not observed in cases where the total area of observed pits is very small and hence, the nonuniformity in the partial current densities is minor and can be ignored.

These examples clearly show that, in the general case, eqn [25] must be used for predicting corrosion potential, at least in the case of steels that are not highly resistant to localized corrosion in the prevailing environment. It is evident that because of the statistical character of pit distribution in size and position, the imposition of charge conservation can be done correctly only by considering propagation of pitting damage as the evolution of an ensemble of pits that initiate, propagate, and repassivate on the metal surface.

## 2.39.5 Rate of Pit Nucleation

### 2.39.5.1 Empirical Models

It would be natural to assume, and experiment confirms this at least for the case of stainless steels, that the rate of nucleation of stable pits,  $n$ , is proportional to the rate of nucleation of metastable pits,  $n_{mp}$ <sup>31–33</sup> that is,

$$n = \zeta n_{mp} \quad [26]$$

where coefficient,  $\zeta$ , can be considered as the probability of nucleation of a stable pit from a metastable pit and is termed the ‘survival probability.’ This parameter can be measured experimentally. Thus, for example, for Type 304L stainless steel in chloride-containing solution, the experimentally measured survival probability has a value of the order of  $10^{-2}$  to  $10^{-4}$ ,<sup>31,32</sup> depending upon the potential and solution conditions. Accordingly, the most probable number of stable pits (per square centimeter),  $N_0$ , will be  $N_0 = \zeta N_{mp,0}$ , where  $N_{mp,0}$  is the most probable number of available sites (per square centimeter) for metastable pits.

In many practical cases, it is possible to assume that all stable pits on a given surface nucleate during an initial period of time that is much smaller than the observation time,  $t$ , or the service life of the system,  $t_s$ . In this case, the process is termed ‘instantaneous nucleation.’ For example, for the case of the pitting

corrosion of aluminum in tap water, as described by Aziz,<sup>10</sup> practically all the pits were found to nucleate within the first 2 weeks (see Figure 1). Under these conditions, the total number of nucleated stable pits (per square centimeter) that nucleate in the time interval between 0 and  $t$  can be simply represented as

$$N(t) = N_0 U_+(t) \quad [27]$$

where  $U_+(t)$  is the asymmetrical unit function ( $U_+ = 0$  at  $t \leq 0$  and  $U_+ = 1$  at  $t > 0$ ).

If pit nucleation cannot be regarded as being ‘instantaneous,’ the simplest assumption concerning the pit nucleation rate of metastable sites,  $n_{mp}(t) = dN_{mp}/dt$ , is that  $n_{mp}(t)$  is proportional to the number of available metastable sites, that is,  $dN_{ms}/dt = [N_{ms,0} - N_{mp}(t)]/t_0$ ,<sup>32</sup> which yields

$$N(t) = N_0 [1 - \exp(-t/t_0)] \quad [28]$$

where  $t_0$  is some characteristic time. It is evident that  $t_0$  must depend on the corrosion potential, temperature, and electrolyte composition, and some experimental data indicating such dependencies can be found in the literature.<sup>31–34</sup> However, no theoretical (deterministic) model has been reported for estimating  $t_0$  as a function of the environmental conditions and the kinetic parameters of the system.

### 2.39.5.2 Point Defect Model

A comprehensive model, in the form of the PDM<sup>35–39</sup> has been developed for estimating the nucleation rate of metastable pits which, when combined with eqn [26], yields the sought-after nucleation rate of stable pits. (Note that only the growth of stable pits gives rise to pitting damage on a surface.) The PDM was originally developed in the early 1980s to provide an atomic scale description of the growth of passive films on a metal surface, but was subsequently expanded to describe metastable passivity breakdown. Thus, it is clearly evident that any deterministic model for describing pit nucleation rate must simultaneously describe the properties of passive films existing on the metal surface and clearly specify the criteria for passivity breakdown itself. The conditions under which passive films exist on metal surfaces are a matter of great theoretical and practical interest, because the phenomenon of passivity is the enabler for our current, metals-based civilization.<sup>21</sup> Thus, our industrial systems and machines are fabricated primarily from the reactive metals and their alloys, including iron, nickel, chromium, aluminum, titanium, copper, zinc, zirconium, stainless steels, nickel-base alloys, and

aluminum alloys, to name a few. Although the phenomenon of ‘passivity’ has been known for about 170 years,<sup>40</sup> and the conditions under which metals and alloys become passive have been systematically explored over the past 70 years, until recently no reasonably unifying theoretical treatment of the limits of passivity has emerged. While many theories and models for the passive state have been developed,<sup>21</sup> most of the presently available models describe an already existing passive film and do not address the conditions under which the film may form or disappear. One of the few attempts to address this issue is the one by Engell,<sup>41</sup> who postulated that passive films can be thermodynamically stable or metastable, with film formation being governed by equilibrium thermodynamics in the first case and by the relative rates of formation and dissolution in the second. While Engell’s work<sup>41</sup> made a valuable contribution to the theory of passivity, it did not resolve the theoretical issues with sufficient precision to allow specification of the exact conditions under which passivation/depassivation might occur (see below).

A comprehensive review of the conditions under which passivity may occur and be lost has been explored within the framework of the PDM by using phase-space analysis (PSA) and can be found in Macdonald.<sup>42</sup> It has been shown that the PDM provides a comprehensive basis for describing the formation and destruction of passive films and hence allows specification of the conditions for the use of reactive metals in our metals-based civilization. A brief description of some results is given below.

The PDM postulates that passive films that form on metal and alloy surfaces in contact with oxidizing environments are bilayer structures comprising a highly (point) defective barrier layer, which grows into the metal and an outer layer that forms via the hydrolysis of cations transmitted through the barrier layer and the subsequent precipitation of a hydroxide, oxyhydroxide, or oxide, depending upon the formation conditions, or by transformation of the outer surface of the barrier layer itself (an ‘Ostwald ripening’ process). In many systems (e.g., Ni and Cr), the barrier layer appears to be substantially responsible for the phenomenon of passivity. In other systems, such as the valve metals and their alloys (Al, Ta, Ti, Nb, Zr), and iron (particularly at elevated temperatures), for example, the outer layer may form a highly resistive coating that effectively separates the reactive metal and the barrier layer from the corrosive environment. The ‘sealing’ of anodized aluminum is an example of how the outer layer may be manipulated to achieve high corrosion resistance. In the present analysis, only the barrier layer is considered, because the passivity of chromium-containing alloys appears to be due to a thin barrier layer of defective  $\text{Cr}_2\text{O}_3$  that forms on the surface in contact with the alloy. Thus, in these cases, the barrier layer is clearly ‘the last line of defense.’

The PDM further postulates that the point defects present in a barrier layer are, in general, cation vacancies ( $V_M^{\chi'}$ ), oxygen vacancies ( $V_O^{\bullet\bullet}$ ), and cation interstitials ( $M_i^{\chi+}$ ), as designated by the Kroger–Vink notation (Figure 4). Cation vacancies are electron acceptors, which result in doping the barrier layer

**Figure 4** Interfacial defect generation/annihilation reactions that are postulated to occur in the growth of anodic barrier oxide films according to the point defect model.<sup>35</sup> M, metal atom;  $V_M^{\chi'}$ , cation vacancy on the metal sublattice of the barrier layer;  $M_i^{\chi+}$ , interstitial cation;  $M_M$ , metal cation on the metal sublattice of the barrier layer;  $V_O^{\bullet\bullet}$ , oxygen vacancy on the oxygen sublattice of the barrier layer;  $O_O$ , oxygen anion on the oxygen sublattice of the barrier layer;  $M^{\Gamma+}$ , metal cation in solution.

p-type, whereas oxygen vacancies and metal interstitials are electron donors, resulting in n-type doping. Thus, on both pure metals and alloys, the barrier layer is essentially a highly doped, point defect semiconductor, as demonstrated by Mott–Schottky analysis<sup>21</sup> for example. Not unexpectedly, the situation with regard to alloys is somewhat more complicated than that for the pure metals. Thus, while the barrier layers on pure chromium and on Fe–Cr–Ni alloys (including the stainless steels) are commonly described as being ‘defective Cr<sub>2</sub>O<sub>3</sub>,’ those on pure chromium are normally p-type in electronic character<sup>43</sup> and those on the stainless steels<sup>44</sup> are n-type. The latter can be described as Cr<sub>2+x</sub>O<sub>3-y</sub>, recognizing that the barrier layer may be metal rich (via metal interstitials) or oxygen-deficient (via oxygen vacancies), or both, whereas that on pure chromium apparently is metal- and oxygen-deficient, or Cr<sub>2-x</sub>O<sub>3-y</sub>, with the cation vacancy being the dominant defect in the system. It is not known whether the apparent differences in the barrier layers on pure chromium and on chromium-containing alloys are due to doping of the barrier layer by other alloying elements, or the inhibition of cation vacancy generation relative to the generation of oxygen vacancies and metal interstitials, in the barrier layer on the alloys compared with that on pure chromium.

The defect structure of the barrier layer can be understood in terms of the set of defect generation and annihilation reactions occurring at the metal–barrier layer interface and at the barrier layer–outer layer (solution) interface, as depicted in Figure 4.<sup>42</sup> Regardless of the electronic type, that is, irrespective of the identity of the dominant defect in the system, reactions [3] and [7] (Figure 4) are responsible for the growth and destruction of the barrier layer and any analysis of the stability of the layer must focus on these two reactions. That the barrier layer always contains oxygen vacancies is self-evident, since the rate of dissolution at the barrier layer–solution interface is always finite.

As noted elsewhere,<sup>21,42</sup> the rate of change of the barrier layer thickness for a barrier layer that forms irreversibly on a metal or alloy surface can be expressed as

$$\frac{dL}{dt} = \Omega k_3^0 e^{a_3 V} e^{b_3 L} e^{c_3 \text{pH}} - \Omega k_7^0 (C_{\text{H}^+} / C_{\text{H}^+}^0)^n e^{a_7 V} e^{c_7 \text{pH}} \quad [29]$$

where  $a_3 = \alpha_3(1 - \alpha)\chi\gamma$ ,  $a_7 = \alpha_7\alpha(\Gamma - \chi)\gamma$ ,  $b_3 = -\alpha_3\chi\epsilon\gamma$ ,  $c_3 = -\alpha_3\chi\beta\gamma$ , and  $c_7 = \alpha_7\beta(\Gamma - \chi)\gamma$ . In these expressions,  $\Omega$  is the mole volume of the barrier layer per cation,  $\epsilon$  is the electric field strength within the

barrier layer (postulated to be a constant and independent of the applied voltage in the steady state, because of the buffering action of Esaki tunneling),<sup>21</sup>  $k_i^0$  and  $\alpha_i$  are the standard rate constant and transfer coefficient, respectively, for the appropriate reactions depicted in Figure 4 (i.e., reactions [3] and [7]),  $\alpha$  is the polarizability of the barrier layer–solution (outer layer) interface (i.e., the dependence of the voltage drop across the interface,  $\phi_{\text{f/s}}$ , on the applied voltage,  $V$ ),  $\beta$  is the dependence of  $\phi_{\text{f/s}}$  on pH (assumed to be linear),  $\gamma = F/RT$ ,  $\chi$  is the oxidation state of the cation in the barrier layer,  $\Gamma$  is the corresponding quantity for the cation in solution,  $C_{\text{H}^+}$  is the concentration of hydrogen ion,  $C_{\text{H}^+}^0$  is the standard state hydrogen ion concentration, and  $n$  is the kinetic order of the barrier layer dissolution reaction with respect to H<sup>+</sup>.

By setting the left side of eqn [29] equal to zero, the steady state thickness of the barrier layer,  $L_{\text{ss}}$ , is readily derived as

$$L_{\text{ss}} = \left[ \frac{1 - \alpha}{\epsilon} - \frac{\alpha\alpha_7}{\alpha_3\epsilon} \left( \frac{\Gamma}{\chi} - 1 \right) \right] V + \left[ \frac{2.303n}{\alpha_3\epsilon\chi\gamma} - \frac{\alpha_7\beta}{\alpha_3\epsilon} \left( \frac{\Gamma}{\chi} - 1 \right) - \frac{\beta}{\epsilon} \right] \text{pH} + \frac{1}{\alpha_3\epsilon\chi\gamma} \ln \left( \frac{k_3^0}{k_7^0} \right) \quad [30]$$

Note that in deriving these expressions, the convention has been adopted that, for the rate of barrier layer dissolution,  $C_{\text{H}^+}$  and  $C_{\text{H}^+}^0$  have units of mol cm<sup>-3</sup>, but when used for defining pH, the units are the conventional mol l<sup>-1</sup>. Thus, the standard states for the dissolution reaction (second term on the right side of eqn [39]) and for the pH are 1.0 mol cm<sup>-3</sup> and 1.0 mol l<sup>-1</sup>, respectively. The introduction of a standard state into the dissolution rate renders the units of  $k_7^0$  independent of the kinetic order,  $n$ , without altering the numerical value of the rate.

The steady state passive current density is readily derived<sup>21</sup> as

$$I_{\text{ss}} = \Gamma F \left[ k_2^0 e^{a_2 V} e^{b_2 L_{\text{ss}}} e^{c_2 \text{pH}} + k_4^0 e^{a_4 V} e^{c_4 \text{pH}} + k_7^0 e^{a_7 V} e^{c_7 \text{pH}} \cdot (C_{\text{H}^+} / C_{\text{H}^+}^0)^n \right] \quad [31]$$

where the first, second, and third terms arise from the generation and transport of cation interstitials, cation vacancies, and oxygen vacancies, respectively, with the term due to the latter being expressed in terms of the rate of dissolution of the barrier layer.<sup>21</sup> This expression is derived, in part, by noting that the fluxes of a given defect at the two interfaces under steady-state conditions are equal; in this way, the

expression for the current can be formulated so as to avoid the defect concentrations at the interfaces.

The passive state is not perfectly protective and, for a variety of reasons, passivity breakdown occurs, resulting in enhanced corrosion rates. Of particular concern is localized passivity breakdown, which results in the nucleation and growth of pits and subsequently, the nucleation and growth of cracks if, the requisite tensile stress is present in the system. A review of the literature reveals the following generalizations of the experimental data for passivity breakdown of metals and alloys in a wide variety of environments<sup>21</sup>:

1. Localized corrosion is initiated by passivity breakdown and occurs on a wide variety of passive metals and alloys in a wide variety of environments.
2. Certain species (e.g.,  $\text{Cl}^-$  and  $\text{Br}^-$ ) induce passivity breakdown by interacting with the barrier layer. These aggressive species apparently do not penetrate through the barrier layer but may be incorporated into the precipitated outer layer.
3. Passivity breakdown occurs at a wide variety of sites on metal and alloy surfaces.
4. Passivity breakdown is a dynamic deterministic process, being predetermined and (in principle) predictable on the basis of known physical laws.
5. The transition of a metastable event to a stable event is a rare event.
6. Two fundamentally different repassivation phenomena may be identified: (i) 'Prompt' repassivation and (ii) 'delayed' repassivation (sometimes referred to as 'stifling').
7. A single passivity breakdown site is characterized by a critical voltage ( $V_c$ ) and induction time ( $t_{\text{ind}}$ ).  $V_c$  is found to be near-normally distributed while  $t_{\text{ind}}$  displays a left acute distribution. The parameters  $V_c$  (and  $\bar{V}_c$ ) and  $t_{\text{ind}}$  exhibit highly characteristic dependencies on the activities of the breakdown-inducing aggressive species ( $a_x$ ) and on the applied voltage ( $t_{\text{ind}}$  only) for a wide variety of systems, suggesting commonality in mechanism.
8.  $V_c$  (and  $\bar{V}_c$ ) is found to depend on the identity of the aggressive ion within a homologous series. Thus, in the case of iron and nickel, the propensities of the halide ions for inducing passivity breakdown lie as  $\text{F}^- < \text{Cl}^- > \text{Br}^- < \text{I}^-$ , whereas, in the case of titanium, bromide ion is the most aggressive. These trends are readily explained by the absorption of the halide into oxygen vacancies in the surface of the barrier layer, with the extent of absorption being determined by the competitive needs to dehydrate the ion and expand the vacancy.<sup>21</sup>
9. The mean breakdown voltage,  $\bar{V}_c$  is found to decrease linearly with  $\log(a_x)$  with a slope that exceeds  $2.303RT/E$  which is attributed to the value of the polarizability of the barrier layer–solution interface lying between 0 and 1, for essentially all systems (metal–solution) that have been investigated. Likewise, the induction time for essentially all systems investigated display a common form of the dependencies of  $\log(t_{\text{ind}})$  on potential and  $[X^-]$ . These relationships strongly suggest commonality in breakdown mechanism.
10. Certain oxyanions (e.g., nitrate, borate, and nitrite) strongly inhibit passivity breakdown, with the effect being accounted for by competitive absorption with the aggressive anion into surface oxygen vacancies in the barrier layer.<sup>21</sup>
11. In many systems (e.g., Al, Ga, Zr, stainless steel), blister formation is observed to be the precursor to passivity breakdown.
12. Certain alloying elements (e.g., Mo in Ni) cause a positive shift in  $V_c$  (and  $\bar{V}_c$ ) and in a lengthening of the induction time. The effect is greater for a larger difference in the oxidation states between the solute and host.
13. Incident electromagnetic radiation, with a photon energy that is greater than the bandgap of the barrier layer oxide also results in a positive shift in  $V_c$  (and  $\bar{V}_c$ ) and in a lengthening of the induction time. The defect (electronic and crystallographic) structures of the barrier layer are modified by irradiation.

It has been shown that PDM is able to explain all the experimental data for passivity breakdown of metals and alloys mentioned above and accordingly, can be considered as providing a suitable theoretical basis for a deterministic model treatment of passivity breakdown and the nucleation of metastable pits in a metal surface.<sup>21</sup>

The PDM, as it relates to passivity breakdown, postulates that certain aggressive anions, for example,  $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{Br}^-$ , and  $\text{I}^-$  absorb into oxygen vacancies in the surface of the barrier layer, resulting in the generation of cation vacancies and hence, to an enhanced flux of the same species across the barrier layer toward the metal–barrier layer interface, as depicted in **Figure 5**. The PDM postulates that if the cation vacancies arriving at the metal–barrier layer interface

**Figure 5** Sequence of events in passivity breakdown, according to the point defect model.<sup>21</sup> Note that the initial event is the absorption of an aggressive anion into an oxygen vacancy at the film–solution interface (a), resulting in an enhanced flux of cation vacancies across the film and eventually in condensation of cation vacancies at the metal–film interface (b). The film stops growing into the metal beneath the cation vacancy condensate while it continues to dissolve at the film–solution interface (c), eventually resulting in rupture (d) and repassivation or the formation of a stable pit (e).

cannot be annihilated at a sufficiently high rate via reaction [1] (Figure 5), the excess vacancies will condense locally and hence cause local separation of the barrier layer from the substrate metal. Once separation has occurred, reaction [3] (Figure 5) can no longer occur so that the barrier layer at that locale is prevented from growing into the metal. However, the barrier layer continues to grow into the metal at the periphery of the cation vacancy condensate and also continues to dissolve at the barrier layer–solution interface. This results in local thinning of the ‘cap’ over the cation vacancy condensate with the cap eventually rupturing because of the growth stresses in the film and in the near-surface substrate. The ‘weak points’ on the surface where passivity breakdown is predicted to occur correspond to regions of high cation vacancy flux. These regions are assumed to be regions of high local discontinuity in the barrier layer, such as the points of intersection of the barrier layer with precipitates, inclusions (e.g., MnS), and other ‘second phase’ particles. Support for this mechanism stems from the almost general observation of the formation of blisters (‘cation vacancy condensate’) as precursors to passivity breakdown on a wide variety of metals and alloys, the passivity breakdown on liquid versus solid gallium, and the potential sweep rate dependence of the apparent breakdown voltage.<sup>21</sup>

The latter evidence is particularly convincing because the test involves no adjustable parameters and yields a quantity (the concentration of condensed vacancies) that can be compared with the same quantity calculated from fundamental principles (crystal structure of the barrier layer).

The description of possible mechanisms for the generation of cation vacancies at the barrier layer–solution interface upon the absorption of the aggressive anion into a positively charged oxygen vacancy in the surface of the barrier layer can be found in Macdonald.<sup>21</sup>

Mathematically, the condition for the initial formation of the cation vacancy condensate can be expressed as<sup>35</sup>

$$(\mathcal{J}_{ca} - \mathcal{J}_m)(t - \tau) \geq \xi \quad [32]$$

where  $\mathcal{J}_{ca}$  is the flux of cation vacancies across the barrier layer at the breakdown site,  $\mathcal{J}_m$  is the annihilation flux (i.e., the rate of reaction [1], Figure 5),  $t$  is the time,  $\tau$  is the dissolution time (see below), and  $\xi$  is the critical areal concentration of vacancies ( $\#/\text{cm}^2$ ). Noting that  $\mathcal{J}_{ca}$  is voltage dependent, the critical breakdown voltage corresponds to that at which breakdown takes an infinite time to occur that is, when  $\mathcal{J}_{ca} = \mathcal{J}_m$ . This condition, in turn, leads to the following expressions for the breakdown voltage and

the induction time for passivity breakdown at a single site on the metal surface as<sup>35</sup>

$$V_C = \frac{4.606RT}{\chi\alpha F} \log \left[ \frac{\mathcal{F}_m}{\mathcal{F}^0 u^{-\chi/2}} \right] - \frac{2.303RT}{\alpha F} \log a_X \quad [33]$$

$$t_{\text{ind}} = \zeta' \left[ \exp \left( \frac{\chi\alpha F \Delta V}{2RT} \right) - 1 \right]^{-1} + \tau \quad [34]$$

where

$$\mathcal{F}^0 = \chi K D [N_v/\Omega]^{1+\chi/2} \exp[-\Delta G_S^0/RT] \quad [35]$$

and

$$u = (N_A/\Omega) \exp[\Delta G_A^0/RT] \exp[-F(\beta pH + \varphi_{f/s}^0)/RT] \quad [36]$$

where  $N_A$  is the Avogadro number,  $\Delta G_S^0$  is the Gibbs energy change for the Schottky-pair reaction,  $\beta$  is the dependence of the potential drop across film–solution interface on pH,  $\varphi_{f/s}^0$  is a constant (potential drop at the film–solution interface for  $V_{\text{app}} = 0$ , and pH = 0) and  $\Delta G_A^0$  is the standard Gibbs energy change for the chloride–oxygen vacancy absorption reaction.

Additionally, the ‘relaxation’ time,  $\tau$ , which is now identified with the time taken for the cap over the vacancy condensate to thin sufficiently for rupture to occur<sup>21</sup> from the point of initial cation vacancy condensation, can be expressed as

$$\tau \leq L_{\text{ss}}/(dL/dt)_{\text{dissolution}} = L_{\text{ss}}/\Omega k_s (C_{\text{H}^+}/C_{\text{H}^+}^0)^n \quad [37]$$

In these expressions,  $L_{\text{ss}}$  is the steady-state thickness

of the barrier layer at the voltage at which cation vacancy condensation just begins. This value is given by eqn [30]. The other parameters are as defined above.

Typical plots of breakdown voltage versus chloride activity, plotted in accordance with eqn [33] are presented in Figure 6. The data labeled ‘PDM’ were calculated from eqn [33] using parameter values estimated by different experiments (primarily from electrochemical impedance spectroscopy, EIS). It should be noted that the PDM has been subjected to numerous experimental tests and, to the authors’ knowledge, no substantial discrepancies have been noted.<sup>21</sup> The model has also been extended to account for transients in barrier layer thickness and passive current in response to potential step and linear potential sweep perturbations. The model has also been extended to account for electrochemical impedance data and, indeed, optimization of the model on impedance data as a function of frequency and voltage has proven to be a very effective way of determining values for various model parameters. Finally, the PDM has also been used to describe the cathodic formation of metal hydride films on metals, such as Li and Zr, and, again, optimization has proven to be an effective means of determining values for model parameters. Discussion of these topics is beyond the

**Figure 6** Plot of the mean critical breakdown potential vs.  $\log(\text{Cl}^- \text{ activity})$  for aluminum in sodium chloride solutions at 25 °C. Experimental data are taken from Kaesche<sup>45</sup> and Böhni and Uhlig.<sup>46</sup>

scope of the present chapter, and the reader is referred to the literature for additional information.<sup>21</sup>

On any real surface, a large number of potential breakdown sites exist, corresponding to a distribution in the properties of the ‘weak spots.’ Thus, examination of data reported by Shibata<sup>47</sup> and Fratesi,<sup>48</sup> among others, suggests that the breakdown voltage is nearly normally distributed. The PDM assumes that the breakdown sites, with respect to the diffusivity of cation vacancies, are described approximately by a normal distribution function,<sup>39</sup> that is,

$$\frac{dN(D)}{dD} = -A \exp \left[ -\frac{(D - \bar{D})^2}{2\sigma_D^2} \right] \quad [38]$$

Here,  $N(D)$  is the number of breakdown sites (per square centimeter) that have diffusivities larger than  $D$ , and  $\bar{D}$  and  $\sigma_D$  are the average value and the standard deviation, respectively, of the diffusivity for the population of the breakdown sites. The negative sign in eqn [38] means that  $N(D)$  decreases with increasing  $D$ . Parameter  $A$  does not depend on  $D$ , so that normalization of the diffusivity distribution using the condition  $N(0) = N_{mp,0}$ , where  $N_{mp,0}$  is the total number of breakdown sites (per square centimeter), yields

$$N(D) = N_{mp,0} \operatorname{erfc} \left( \frac{D - \bar{D}}{\sqrt{2}\sigma_D} \right) / \operatorname{erfc} \left( -\frac{\bar{D}}{\sqrt{2}\sigma_D} \right) \quad [39]$$

Because the transport of cation vacancies across the barrier layer from the barrier layer–solution interface to the metal–barrier layer interface occurs primarily by electro-migration, the cation vacancy flux density,  $\mathcal{J}_{ca}$ , is proportional to the diffusion coefficient of the vacancies,  $D$ , that is,

$$\mathcal{J}_{ca} = DB \quad [40]$$

where the function  $B$  depends on the external conditions (applied voltage,  $V_{app}$ , temperature,  $T$ , chloride activity,  $a_{cl}$ , etc.) and on the electric field strength within the film. Thus, for the case of passivity breakdown in a solution containing an aggressive anion,  $X^-$  (e.g., chloride ion), the PDM yields

$$B = \hat{a} u^{-\chi/2} \exp \left( \frac{\chi F \alpha V_{app}}{2RT} \right) a_x^{\chi/2} \quad [41]$$

where  $\alpha$  is the polarizability of the film–solution interface (i.e., dependence of the potential drop across the barrier layer–solution interface on the applied potential),  $\chi$  is the cation oxidation state in the barrier layer,  $R$  is the gas constant, and  $F$  is

Faraday’s constant. In turn, parameters  $\hat{a}$  and  $u$  are defined as<sup>35</sup>

$$\hat{a} = \chi(F\varepsilon/RT)[N_A/\Omega]^{1+\chi/2} \exp(-\Delta G_s^0/RT) \quad [42]$$

where parameter  $u$  is defined by eqn [36].

Substituting eqns [40] into eqn [32] yields the following criterion for metastable pit nucleation as

$$D \geq D_{cr} = \frac{\xi + \mathcal{J}_m(t - \tau)}{B(t - \tau)} \quad [43]$$

Criterion [43] states that the nucleation of metastable pits occurs within the observation time,  $t$ , on those and only those sites that have  $D \geq D_{cr}$ . From Equations [26], [39], and [43], we have

$$N(t) = N_0 \operatorname{erfc} \left( \frac{a}{t - \tau} + b \right) / \operatorname{erfc}(b) \quad [44]$$

where  $a = \xi/(B\sqrt{2}\sigma_D)$ , and  $b = (\mathcal{J}_m/B - \bar{D})/(\sqrt{2}\sigma_D)$ . Accordingly, for the rate of pit nucleation, we obtain the following expression,

$$n(t) = \frac{dN}{dt} = \frac{N_0 2a}{\operatorname{erfc}(b)\sqrt{\pi}} \frac{\exp \left[ -\left( \frac{a}{t - \tau} + b \right)^2 \right]}{(t - \tau)^2} \quad [45]$$

It is important to note that, in accordance with eqn [28], the maximum pit nucleation rate must be observed at the beginning of corrosion attack, that is, at  $t = 0$ . On the other hand, in accordance with PDM, as follows from eqn [45], the maximum pit nucleation rate must be observed at

$$t_{max} = a \left( b + \sqrt{b^2 + 4} \right) / 2 \quad [46]$$

Accordingly, if observation time,  $t$  (service life  $t_s$ ), satisfies the condition

$$t \gg t_{max} \quad [47]$$

practically all pits nucleate during a very short period of time at the beginning of the observation time, that is, the PDM predicts the case of instantaneous nucleation. Calculation shows<sup>13</sup> that, in some cases (especially at high concentrations of  $Cl^-$ ) criterion [47] holds very well and the nucleation of pits on a metal surface may be regarded as an ‘instantaneous nucleation’ phenomenon. However,  $t_{max}$ , increases very sharply with decreasing chloride concentration, leading to the case of progressive nucleation, in which new pits nucleate on the surface as existing pits grow and die (repassivate). The fact that the surface concentration of pits grows at a maximum rate after the appearance of the first pit has been experimentally observed, for example,

the case of the pitting corrosion of passive iron in borate buffer solution containing chloride ion.<sup>49</sup>

### 2.39.6 Rate of Pit (Cavity) Propagation

The quantitative description of pit (or cavity) growth remains one of the key problems in predicting corrosion damage in many practical systems. This follows from the fact that the calculated corrosion damage that is based only on this (growth) stage can be compared with experiments in many limiting cases. For example, in the case of pitting corrosion, when all pits nucleate ‘instantaneously,’ or when the induction time for pit nucleation is much smaller than the observation time, it is possible to ignore the initial stage of pit nucleation when estimating the damage. In addition, if the probability of survival of a corrosion defect is sufficiently high, we must take into account the possibility that a stable corrosion defect (pit or crack) nucleates immediately after the start of operation and propagates without repassivation and hence, the same defect that nucleated in the beginning is still active at the end of the observation time. In any case, calculations based only on the growth stage yield the most conservative estimate of the service life,  $t_{s,\min}$ , of the system. We can be sure that if calculation of the service life is based on growth alone, the real service life,  $t_s$ , will at least be not less than  $t_{s,\min}$ .

Moreover, it is also natural to assume that the rate of propagation of an individual pit (crack) without neighbors will be greater than that for the same pit (crack) with neighbors (i.e., within an ensemble of pits (cracks)), because the neighboring pits reduce the potential at the surface and multiple, neighboring cracks are expected to reduce the stress intensity factor experienced by a single crack for a given loading stress. Accordingly, the proper modeling of propagation of individual corrosion defects can yield the possible minimum survival time for the system as a whole (e.g., a machine). If this time extends beyond the projected service life of the system, we can be sure that the system will survive under real conditions.

#### 2.39.6.1 General Approach for Calculating Propagation Rates

Apparently, one of the main theoretical problems in describing localized corrosion damage is the prediction of the shape and dimensions of corrosion

cavities at any time as a function of the parameters controlling the process (potential of the metal, species concentrations, such as velocity of the electrolyte, thickness of the passive film, diameter of the pit mouth, etc.). It seems obvious that mathematical models describing the pit (cavity) growth should start with the assumption that the pit form and size are not known *a priori*, but should be found during the solution of the appropriate equations.

From the mathematical point of view, the problem of determining the shape and size of a developing pit belongs to the class of Stefan problems.<sup>50</sup> These problems are reduced to the solution of the system differential equations of parabolic or elliptic type with unknown boundary conditions because the velocity of this boundary is connected to the sought after solution by some differential relationship.

The implicit equation  $\Phi(t, x_1, x_2, x_3) = 0$  shall describe the pit surface with time, relative to the Cartesian coordinate system  $x_1, x_2, x_3$ . This expression fulfills the relation  $d\Phi = (\partial\Phi/\partial t + \nabla\Phi \cdot V_s)dt = 0$ , where  $V_s(t, dx_1/dt, dx_2/dt, dx_3/dt)$  is the velocity of the dissolving metal surface. In this formulation, subscript refers to the electrode surface and subscript  $\infty$  to the bulk of the solution. Let  $\vec{n} = \nabla\Phi/|\nabla\Phi|$  be a unit vector pointing normally from the solution to the metal surface. According to Faraday’s law,  $V_s = K_v i_{\text{corr}} \vec{n}$ , where  $i_{\text{corr}}$  is the current density for metal dissolution, and  $K_v$  is the electrochemical equivalent volume, that is, the volume of dissolving metal when one Faraday of charge (96 487 int. coulombs) passes through the interface.

Introducing the correlation for  $V_s$  into the expression for the differential  $d\Phi$  yields an equation describing the change of the electrode surface

$$\frac{\partial\Phi}{\partial t} + K_v i_{\text{corr}} |\nabla\Phi| = 0 \quad [48]$$

Equation [48] is frequently used to describe some important processes in electrochemical technology, for example, electrochemical machining of metals, electrochemical shape formation, and so on.<sup>51</sup> Of course, we can also expect that, in the general case, some additional component, not connected with metal dissolution (e.g., due to mechanical spallation at very high fluid velocities or hydrogen embrittlement) should be incorporated into the expression for the  $V_s$ , but this issue is not germane to the present discussion and will not be considered further here.

Besides the information about the boundary position in the initial period,  $\Phi(0, x_1, x_2, x_3)$ , the integration of eqn [48] requires information about the

dissolution current density,  $i_{\text{corr}}$  that is, eqn [48] must be solved with a set of nonstationary equations for mass balance for each component in the solution, namely

$$\frac{\partial c_k}{\partial t} = -\nabla \cdot \vec{J}_k + R_k; \quad k = 1, \dots, K \quad [49]$$

where  $C_k$  is the concentration of species  $k$ ,  $\vec{J}_k$  is the flux density of species  $k$ , and  $R_k$  is the rate of production (source) or depletion (sink) of this species as a result of homogeneous chemical reactions. The current density,  $\vec{i}$ , in the electrolyte solution is defined as

$$\vec{i} = F \sum_k z_k \vec{J}_k \quad [50]$$

In the vast majority of practical applications, dilute solution theory is used to calculate the flux of the species, that is,

$$\vec{J}_k = -D_k \nabla C_k - z_k F u_k C_k \nabla \phi + C_k \vec{v} \quad [51]$$

where  $\phi$  is the electrostatic potential in the solution,  $v$  is the fluid (hydrodynamic) velocity, and  $u_k$  is the mobility of species  $k$ , which can be estimated by using the Nernst–Einstein equation:

$$u_k = \frac{D_k}{RT} \quad [52]$$

In eqn [51], the first term on the right-hand side represents the contributions of diffusion, the second term describes migration, and the third term is a contribution of convection. An additional condition for determining the electrostatic potential is the equation

$$\sum_k z_k C_k = 0 \quad [53]$$

It must be noted that, generally speaking, the condition of electroneutrality is not a law of nature and can be considered as an approximation of Poisson's equation:

$$\nabla^2 \phi = -\frac{F}{\varepsilon} \sum_k z_k C_k \quad [54]$$

where  $\varepsilon$  is the dielectric permittivity (dielectric constant multiplied by the permittivity of free space) of the solution. However, due to the large value of the ratio  $F/\varepsilon$ , an appreciable separation of charge would require unrealistically large electric forces. Visible deviation from electroneutrality can be observed only in a very thin double layer near an electrode surface (which is of the order of 1–10 nm in thickness) or within a doped semiconductor junction that can be taken into account in the boundary

conditions for the problem. Accordingly, the electro-neutrality approximation is fulfilled very well, and is widely accepted by the electrochemical community.<sup>52</sup> In spite of this fact, some papers where Poisson's equation is used directly can be found in the literature.<sup>53</sup> In accordance with our opinion, this approach introduces only unnecessary complications, due to excessive calculational time.

The hydrodynamic velocity,  $\vec{v}$ , within the framework of dilute solution theory, can be found apart from the solution of the mass transfer problem by using the corresponding mechanical equations (e.g., the Navier–Stokes equations, in the case of laminar flow<sup>52,54</sup>). In the case of turbulent flow, which often exists outside the corrosion cavity, it is convenient to use some effective diffusion coefficient instead of the usual diffusion coefficient,  $D_k$ ,

$$D_k^{\text{eff}} = D_k + D_t \quad [55]$$

where diffusion coefficient  $D_t$  depends on the distance from the wall, hydrodynamic conditions, and the physical properties of the liquid. Some empirical correlations for  $D_t$  can be found in the literature.<sup>52,54,55</sup>

Strictly speaking, eqn [51] for species flux densities is valid in the case of dilute solutions. In the case of concentrated solutions, eqn [51] should be replaced by

$$\vec{J}_k = C_k \vec{v}_k \quad [56]$$

where the velocity,  $\vec{v}_k$ , of species  $k$  can be found from the equation of multicomponent diffusion.<sup>52</sup>

$$C_k \nabla \mu_k = RT \sum_i \frac{C_k C_i}{C_T D_{ki}} (\vec{v}_i - \vec{v}_k) \quad [57]$$

where  $\mu_k$  is the electrochemical potential of species  $k$ ,  $D_{ij}$  are diffusion coefficients, and  $C_T$  is the sum of all concentrations of all components, including the solvent. However, in the literature, there are no significant applications of the theoretical principles describing transport in concentrated solutions for the case of corrosion, with the exception of the preliminary work of Popov *et al.*<sup>56</sup> The reasons for this state of affairs are the increased complexity of the theory and the lack of appropriate input data for practical application.

However, it is important to note that, in the overwhelming majority of corroding systems, the concentrations of all solute species,  $C_k$ , are much smaller than the concentration of the solvent,  $C_0$ . Under these

conditions, only one term on the right side of eqn [50] is important. Accordingly, eqn [57] can be rewritten in the following form for the theory of moderately dilute solutions<sup>52</sup>

$$\vec{J}_k = -D_k \nabla \mu_k + C_k \vec{v} \quad [58]$$

If we present  $\mu_k$  in the form

$$\mu_k = RT \ln(\gamma_k C_k) + z_k F \varphi \quad [59]$$

where the activity coefficient,  $\gamma_k$ , depends on the concentration of all species in the solution, the equation of the flux becomes

$$\vec{J}_k = -D_k \nabla C_k - \frac{D_k z_k F}{RT} C_k \nabla \phi + C_k \vec{v} - D_k C_k \nabla \ln(\gamma_k) \quad [60]$$

This equation for ion flux densities has been used, for example, in Walton *et al.*<sup>57</sup> for describing crevice corrosion. However, the activity coefficients in Walton *et al.*<sup>57</sup> are calculated within the framework of Debye–Hückel theory that, is strictly speaking, applicable only for the case of dilute solutions.

We would like to emphasize that, in many real corrosion systems, the concentration drops within a corroding cavity may be not very high, because corrosion is not a fast process. Accordingly, eqn [1] can be used with sufficient accuracy in relatively concentrated solutions, assuming that  $D_k$  is referred to the bulk electrolyte, but not to infinitely dilute solutions.

In accordance with the rules, the homogeneous terms,  $R_k$ , in the balance equations can be written in general form as

$$R_k = \sum_{m=1}^M \left[ -k_m v_{km} \left\{ \prod_{v_{km}>0} C_k^{v_{km}} - K_m \prod_{v_{km}<0} C_k^{-v_{km}} \right\} \right] \quad [61]$$

where  $k_m$  is the rate constant of reaction  $m$ ,  $\sum_k v_{km} M_k = 0$  ( $m=1,2,\dots,M$ ),  $K_m$  is the equilibrium constant for reaction  $m$ ,  $v_{km}$  is the stoichiometric coefficient for species  $k$  in  $m$ th chemical reaction, and  $M_k$  is the symbol for the chemical formula of species  $k$ .

The presence of the chemical terms in balance eqns [49] greatly complicates their solution. First of all, we have practically no information about the rates of homogeneous reactions (usually, we only have information about their equilibrium constants). However, we can reasonably assume that these reactions are fast and they are practically in equilibrium at any given point and time. The most widely applied

method for dealing with these problems is to eliminate chemical terms by adding or subtracting balance eqns [49]. The new set of governing equations is then supplemented by equations of equilibrium.<sup>58</sup> The great disadvantage of this approach is as follows. Every time, we want to add or delete from consideration any chemical reaction, we have to completely change the computer code for numerical solution of balance equations because of their change in form. Moreover, the forms of these equations do not coincide with the standard form of the equation of mass balance, and this adds to the complexity of the process of numerical solution.

The alternative approach for modeling the equilibrium state is to keep the governing equation in rate format (i.e., in the form of eqn [49]), and hence to assume that reactions are very fast. As long as reaction rates are large, relative to the rates of mass transport, the reactions will remain at equilibrium, and the solution composition will be independent of the kinetics assumed. All kinetic expressions that are physically consistent (i.e., are stoichiometrically true) yield zero net reaction at equilibrium, change sign as the equilibrium point is crossed, and give sufficiently fast reaction rates that can be used.<sup>59</sup> The choice becomes a matter of numerical stability and convenience. Therefore, Walton<sup>60</sup> used the following expression for the rate of production or depletion of species  $k$  by the chemical reaction

$$R_k = \sum_{m=1}^M \left[ -r_m v_{km} \ln \left\{ \prod_{k=1}^K C_k^{v_{km}} / K_m \right\} \right] \quad [62]$$

which satisfies all of the conditions noted above.

Another alternative approach is the following.<sup>57,61</sup> It is assumed that characteristic times of chemical reactions in aqueous solution are much shorter than those of the mass transport or corrosion processes, which is equivalent to assuming high reaction rates. Accordingly, the set of transport equations are first solved separately from the chemical terms. After that, at the end of each sufficiently small time step, the resulting aqueous solution composition, within each elementary volume, is solved to equilibrium by calling an equilibrium solver. For example Walton *et al.*<sup>57</sup> determined the equilibrium composition of the solution by Gibbs free energy minimization.

The homogeneous terms,  $R_k$ , in the balance equations can be written in a general form as: It is assumed that at a point far away from the mouth of a pit or crevice, the concentrations and potentials have their bulk values, that is,

$$C_k = C_{k,\infty}; \phi = \phi_\infty = 0 \quad [63]$$

It is also assumed that the normal fluxes on the solid surface,  $\mathcal{J}_{ks}$ , can be expressed as a known function of surface temperature,  $T_s$ , surface concentrations,  $C_{ks}$ , and surface potential,  $E_{\text{corr}} - \phi_s$ , (on the metal surface), that is,

$$-D_k \frac{\partial C_k}{\partial n} = \mathcal{J}_{ks}(E_{\text{corr}} - \phi, C_{1,s}, C_{2,s}, \dots, C_{K,s}, T_s) \quad [64]$$

If some component does not participate in any heterogeneous reaction (chemical or electrochemical), its flux density will be equal to zero. Of course, on an insulator, all fluxes are equal to zero.

In formulating the initial conditions, it would be natural to assume that concentrations of all species and potentials coincide with the corresponding bulk values at  $t = 0$ . However, simple calculation shows that, under normal conditions, the velocity of the interface is so slow that the steady-state approximation can be used for describing the transport processes for the anodic dissolution of the metal.<sup>50,51</sup>

The sense of this approximation is as follows: The movement of the metal surface is so slow that the concentration distribution in the solution is approximately that corresponding to steady flow at a given position of the boundary and for given boundary conditions. In this case, it is possible to omit the derivative over time in balance, eqn [49]. Accordingly, it is possible to separate the solution of the mass transfer problem from the movement of the boundary. After solving the steady-state problem in the region with the fixed boundaries, and after calculating the corrosion current density, the new position of the metal surface is found by using Faraday's law (see eqn [48]). After that, the solution of the steady problem for the new boundary is found, and the process is repeated until the desired time is achieved. Of course, it is not possible to omit the derivative over time in the balance equation in the case of corrosion fatigue, caused by the sharply changing hydrodynamic velocity, which is a result of periodic loading.

However, it must be noted that there are a very limited number of studies where the problem of pit propagation is regarded as a problem having a free boundary in multidimension space. Practically, (in multidimension space) consideration of a moving boundary is limited to the simplest cases, when the system of transport equations can be reduced to the solution of a single Laplace equation for the

relative concentration of a single species<sup>62</sup> or electric potential.<sup>63</sup>

On the other hand, such problems are successfully solved in heat transfer studies, for example, in connection with the problem of metal ingot solidification.<sup>64</sup> The presence of migration is the fundamental difference between the problems of ionic transport and those in nonelectrolyte solutions or problems in heat transfer. This difference does not permit the direct use of a wide range of methods and computer programs that have been developed in connection with the problems of heat transfer for solving ion transport problems. As a result, to solve each ion transport problem, for example, using the so-called Newman method,<sup>52</sup> it is necessary to create new programs that require substantial expenditure of time and effort.

It is also possible to use iterative methods to reduce ion transport problems to a sequence of transport problems for nonelectrolyte solutions, which enables one to directly use the methods and even the existing computer programs available in heat engineering.<sup>65-67</sup>

The very useful method of quasipotential transformation for modeling transport processes in dilute electrochemical systems has been developed by Pillay and Newman.<sup>68</sup> It can be shown that, under steady-state quiescent conditions, with equilibrium homogeneous chemical reactions, and for a single electrochemical reaction, the electrostatic potential and all concentration distributions can be represented as a single-valued harmonic function of the quasipotential,  $q$ . This harmonic function vanishes at infinity and satisfies the following boundary conditions

$$\frac{\partial q}{\partial n} = 0 \quad [65]$$

at an insulating surface, and

$$-\frac{\partial q}{\partial n} = i \quad [66]$$

at an electrode (conducting) surface, where  $\mathbf{n}$  is the unit normal vector at the electrode surface pointed towards the solution. Accordingly, the set of coupled second-order, nonlinear partial differential equations governing mass transfer by diffusion and migration in electrochemical systems is transformed into Laplace's equation for the quasipotential and hence, into a set of coupled, first-order nonlinear ordinary differential equations. This method has been applied to the case of the development of an active hemispherical pit.<sup>69</sup> Unfortunately, this method cannot be generalized, for example, for the nonstationary case, for the case of

multiple electrochemical reactions, or for mass transfer in flowing electrolytes.

It is also important to note that, at the present time, commercial software is available for solving transport equations with migration terms with fixed boundaries (see, e.g., COMSOL software),<sup>70</sup> although some algorithms also handle moving boundaries now. Accordingly, the most difficult problem that arises very often during the solution of mass transfer problems is not the solution of the differential equations themselves, but in defining the transport coefficients (e.g., diffusion coefficients) in multicomponent systems, rates of chemical reactions, and especially in establishing real kinetic relations for the species fluxes on the metal surfaces (particularly for the rate of metal dissolution), such as those contained in eqn [64]. The concrete dependencies of the rates of corrosion propagation as a function of potential, concentrations of species near the metal surface, and mechanical conditions for the cases of pitting corrosion, stress corrosion cracking, corrosion fatigue, crevice corrosion, etc. are discussed in the corresponding chapters of this book. Commercial software for calculating transport properties (diffusion coefficients, activities, viscosities, density rates of particular electrochemical reactions on particular metals and alloys) is also available (see, e.g., OLI Systems software).<sup>71</sup>

A detailed review of a great number of papers dealing with mathematical modeling of transport phenomenon in pitting and crevice corrosion is presented, for example, in Turnbull,<sup>58</sup> Sharland,<sup>61</sup> Papavinosan *et al.*<sup>72</sup> In the majority of these models, instead of boundary conditions [64], the boundary conditions of the Type II kind (i.e., prescription of current density on the metal surface) are employed. In the latter case, the principal aim of these models is not to predict corrosion damage (corrosion rates are assumed to be known in advance), but to estimate species concentrations, and the potential distribution in corrosion cavities, as a function of many parameters like cavity dimension, bulk solution composition, temperature, and so on. Very often such models serve to aid in the understanding of results of particular experimental systems. However, at present, the overwhelming majority of the models devoted to estimating the size of a corrosion cavity have adopted the one-dimensional approximation, that is, they are reduced to calculating the depth of the cavity,  $a$ , as a function of time, when eqn [48] is reduced to the simplest relation

$$\frac{da}{dt} = K_V i_{\text{corr}} \quad [67]$$

Because of the mathematical complexity of the problem, analyses of the transfer processes occurring within corrosion cavities have generally employed the one-dimensional approximation. For example, it is often assumed, in the case of corrosion pits, that the cavity has a cylindrical shape with a depth  $a$ , which is much larger than the radius,  $r$ . Likewise, crevices and cracks are often viewed as being one-dimensional slots of length  $a$ , such that  $a$  is much greater than the opening displacement,  $w$ .<sup>57,60,61,73–82</sup> Very often, only metal dissolution at the bottom is assumed. However, two-dimensional analyses of corroding hemispherical pits have been described for the case of a well mixed electrolyte by Newman *et al.*,<sup>83</sup> and for the case of a quiescent system, in which concentration gradients exist.<sup>63,69,84</sup> In many cases, the results obtained by mathematical simulation or by experimental studies of ‘ideal’ cells (one-dimensional or hemispherical) have been used to describe corrosion processes under real conditions.

In the one-dimensional case, the balance equations are reduced to the form

$$\frac{\partial(wC_k)}{\partial t} = -\frac{\partial w\mathcal{F}_k}{\partial x} + wR_k + \mathcal{F}_{S1} + \mathcal{F}_{S2}, \quad [68]$$

$$k = 1, 2, \dots, K$$

where  $\mathcal{F}_k$  is the flux density along the direction down the crevice,  $x$ , averaged over the width of the crevice,  $w$ ,  $\mathcal{F}_{S1}$  and  $\mathcal{F}_{S2}$  are the flux densities at a metal–solution interface or on the side walls (usually it is assumed that  $\mathcal{F}_{S1} = \mathcal{F}_{S2}$ ). In the case of the cylindrical pit of radius,  $r$ , we simply have

$$\frac{\partial C_k}{\partial t} = -\frac{\partial \mathcal{F}_k}{\partial x} + R_k + 2\mathcal{F}_S/a, \quad k = 1, 2, \dots, K \quad [69]$$

It must be emphasized that, in the overwhelming majority of the work devoted to describing localized corrosion in the one-dimensional approximation, it has been tacitly assumed that it is possible to neglect the potential drop in the external environment (outside the corrosion cavity), that is, to assume that boundary conditions [56] are fulfilled at the mouth of the crevice. The following section will show that such an approximation is incorrect from the physical point of view and in many cases can lead to significant errors in the estimation of corrosion damage.

### 2.39.6.2 Coupled Environment Corrosion Cavity Growth Models

Many localized corrosion processes, including pitting, stress corrosion cracking, corrosion fatigue, and crevice corrosion may be described within the framework of the differential aeration hypothesis (DAH), which was first postulated by U. R. Evans in the 1920s.<sup>85</sup> This postulate attributes localized corrosion to a spatial separation of the local anode and local cathode, with the local anode occurring in that region of the system that has the least access to the cathodic depolarizer (e.g., oxygen), while the local cathode occurs in that region that has the greatest access to the cathodic depolarizer. In the case of a pit or a crack, as depicted schematically in Figure 7, the local anode exists within the cavity, whereas the local cathode exists on the bold external surfaces.

The voltage difference generated between the cavity and the external surface causes a positive current to flow through the solution from the local anode to the local cathode. Negative electron current flows through the metal in the reverse direction and the two currents mutually annihilate at the

**Figure 7** Coupling of crack internal and external environments. Note that in the steady state, the crack can grow only as fast as the positive current flowing from the crack can be consumed on the external surfaces by oxygen reduction. Reproduced from Macdonald, D. D.; Lu, P.-C.; Urquidí-Macdonald, M.; Yeh, T.-K. *Corrosion* **1996**, 52, 768.

external surface via a charge transfer reaction, in this case, the reduction of oxygen. The current is known as the ‘coupling current’ and is easily measured.<sup>86</sup> The coupling current has been shown to contain a wealth of information concerning the processes that occur within the cavity. The coupling current is generated within the cavity by anodic oxidation of the metal that may be unassisted by mechanical processes (pitting corrosion and crevice corrosion) or assisted by the presence of a constant stress (stress corrosion cracking, SCC) or a cyclic stress (corrosion fatigue, CF). In any event, the flow of positive current out of the cavity occurs because of the existence of a potential gradient in the solution from the cavity tip to the cavity mouth, such that  $\phi_t > \phi_m > \phi_\infty$ , where  $\phi_t$ ,  $\phi_m$  and  $\phi_\infty$  are the corresponding electrostatic potentials in the solution at the cavity tip, cavity mouth, and at a point on the external surface that is at an effectively infinite distance from the mouth (i.e., the ‘throwing power,’ which turns out to be about 10–20 crack mouth opening displacements, but which also depends upon the conductivity of the environment). The sign of this potential gradient is such that anions are transported into the crack, where they neutralize the positive charge that is injected into the cavity solution in the form of metal cations. The metal cations hydrolyze to produce protons that acidify the environment. The concentration factors for both  $\text{Cl}^-$  and  $\text{H}^+$  from electromigration and hydrolysis, respectively, can exceed  $10^4$ . Thus, for an environment containing 10 ppb of chloride ion and having a pH of 7, the chloride concentration and pH in the cavity may exceed 100 ppm and below 3, respectively. Accordingly, noting the propensity of chloride ions to induce passivity breakdown, the DAH accounts for the development of aggressive conditions within the cavity, even though the external conditions might be quite benign.

It is evident that, under free corrosion conditions, the conservation of charge requires that the charge passed by the cathodic reaction be matched by the charge passed by the partial anodic reaction (see eqn [25]). Recognizing that, at sufficiently large distances from the crack mouth on the external surface, the net current,  $i_N = i_a + i_c$  ( $i_a$  and  $i_c$  are the local anodic and cathodic partial current densities) must be zero, corresponding to ‘free,’ general corrosion, the partial current density distributions are such that eqn [25] must be satisfied. Note that eqn [25] does not stipulate that cathodic partial reactions cannot occur within the cavity or that anodic partial reactions cannot occur on the external surfaces; only that, in the ‘cathodic’ and

‘anodic’ regions, the net current densities are negative and positive, respectively, and the total currents integrated over the respective areas are equal.

It is also important to glean an understanding of the critical nature of the properties that exist at the crack mouth. Thus, note that solving the entire problem involves solving two closely coupled sub problems, one for the external environment and the other for the crack enclave. These two problems are coupled because they share common boundary conditions in potential,  $\phi_m$ , and in current,  $i_m$ . The objective in all coupled environment models (CEMs) developed to date has been to find the appropriate values for  $\phi_m$  and  $i_m$ , such that eqn [25] is satisfied. It is the constraint imposed by eqn [25] that imparts determinism to the model.

Traditionally, models for localized corrosion cavity growth have assumed that the electrical potential in the solution at the crack mouth is the negative of the free corrosion potential or that the external environment presents no impedance to current flow (i.e., the current may flow to infinity). Neither postulate is correct. In the first case, no potential gradient would exist in the external environment and hence, the coupling current must be zero, contrary to experimental observation. Indeed, these models actually predict that SCC cannot occur. In the second case, if there exists no impedance for current flow to infinity, then there should be no dependence of the coupling current and crack growth rate on the catalytic properties of neighboring external surfaces, again contrary to experiment. The requirement that the underlying theory must account for all of the experimental observations is therefore not met by both classes of models. However, the authors note that the assumptions may be valuable approximations in solving the mass transport equations for the cavity, but, in doing so, it must be recognized that in ignoring the external environment, the physical description of the system is incomplete. Accordingly, and emphasizing again that a viable model must account for all experimental observations, such an approach would fail to recognize the important impact that catalysis or inhibition of oxygen reduction on the external surfaces has on crack growth rate in sensitized Type 304 SS in high temperature water, as noted above.<sup>87,88</sup>

To date, we<sup>86,89–95</sup> and others<sup>96,97</sup> have developed ‘coupled environment’ models for stress corrosion cracking (coupled environment fracture model, CEFM<sup>89,90,92,93</sup>), corrosion fatigue (coupled environment corrosion fatigue model, CECFM<sup>94</sup>), pitting

(coupled environment pitting model, CEPF<sup>91</sup>), and crevice corrosion (coupled environment crevice model, CECM<sup>95</sup>). Details of the algorithms are not given here as they have been adequately described in the literature. In the interests of space, only a brief outline of some of the results from the CEFM is given. We note that alternate models for crack growth in sensitized stainless steels have been developed by others, most notably by Ford and coworkers,<sup>98,99</sup> Shoji,<sup>100,101</sup> and Vankeerberghen and Gavrilov.<sup>102</sup> Of these models, only the model of Vankeerberghen and Gavrilov<sup>102</sup> constrains the solution by the conservation of charge and hence, can be regarded as being deterministic. The models of Shoji<sup>100,101,103</sup> are essentially mechanical in form, with any electrochemistry being introduced ‘inadvertently,’ and, like Ford *et al.*’s models,<sup>98,99</sup> while they are ‘mechanistic,’ they fail to be constrained by the relevant natural law (conservation of charge), recognizing that IGSCC is primarily an electrochemical phenomenon.

The first of the CEMs to be developed was the coupled environment models (CEMs) in 1991.<sup>89</sup> Since then, the model has been extensively developed by the authors and their colleagues as a deterministic model for predicting stress corrosion crack growth rate in a variety of systems, including the coolant circuits of water-cooled nuclear reactors.<sup>104</sup> The models are based upon the following general experimental observations that apply strictly to the growth of intergranular cracks in sensitized Type 304 SS in high temperature water, but that are believed to be general correlations for SCC and other forms of localized corrosion in other systems:

- Localized corrosion generally follows the differential aeration hypothesis, first proposed by Evans in the 1920s.<sup>85</sup>
- A positive coupling current is observed to flow through the solution from the crack mouth to the external surfaces, while an equal but opposite electron current flows through the metal in the reverse direction.<sup>86</sup>
- The crack growth rate increases roughly exponentially with the potential of the metal if it is sufficiently high. At lower potentials, the CGR is potential-independent, corresponding to the mechanical creep (Figure 8).<sup>90–101,103</sup>
- The CGR depends upon the electrochemical crack length, which is defined as the shortest distance between the crack front and the exposed external surface. This length is generally different from the mechanical loading crack length.<sup>90,102</sup>

**Figure 8** Measured and analytically calculated crack growth rate of sensitized Type 304 stainless steel as a function of corrosion potential. Calculations were done using the Congleton's correlation for the crack-tip strain rate. Experimental data were taken from Ford *et al.*<sup>99</sup>

- The environmentally-mediated CGR is proportional to the magnitude of the coupling current.<sup>87,105</sup>
- Coating the external surfaces with an insulator, and hence inhibiting the reduction of oxygen, causes the coupling current to decrease sharply and stops the crack from growing.<sup>87</sup>
- Catalyzing the reduction of oxygen on the external surface results in an increase in the coupling current and hence, an increase in the CGR.<sup>86,88</sup>
- The crack growth rate passes through a maximum with increasing temperature at about 175 °C.<sup>106</sup>

It is well known that, in the fracture of sensitized stainless steels and nickel alloys in high temperature (250–300 °C), oxidizing aqueous media, the CGR becomes independent of potential at sufficiently negative ECP values (see [Figure 8](#)) and that the fracture morphology changes from intergranular brittle fracture to ductile failure. The ductile fracture surfaces frequently yield evidence of microvoid coalescence, with ductile tearing of the matrix between the voids. These voids appear to nucleate at intergranular precipitates, such as carbides (e.g., Cr<sub>23</sub>C<sub>7</sub>) on the grain boundaries, but nucleation at intragranular precipitates is also observed. Thus, in the CEFM, which was developed originally to describe fracture in sensitized stainless steels in BWR primary heat

transport circuits,<sup>83,84,90</sup> it seemed appropriate to describe crack growth at the 'creep' limit in terms of a cavitation model.

A modified version of the cavitation model developed by Wilkinson and Vitek<sup>107</sup> was used to estimate CGR at sufficiently negative potentials, where environmental effects are not evident. A detailed account of the creep model will not be given here and the reader is referred to the original paper by Wilkinson and Vitek<sup>107</sup> and papers by Macdonald *et al.*<sup>90,93,108</sup> describing the application of the model in the CEFM. It suffices to note that the Wilkinson–Vitek model accurately describes creep crack growth in stainless steels over the temperature range of interest (25–300 °C).

The numerical and analytical solutions employed in the CEFM yield very reasonable results for the environmentally assisted and creep fracture of sensitized Type 304 SS,<sup>89</sup> and have yet to yield a prediction of crack growth rate that is at odds (i.e., lies outside the experimental error range) with experiment. The calibration factor appears to take care of a number of simplifying assumptions in the numerical CEFM (e.g., inert crack walls and linear potential drop down the crack) and compensates for some less quantified effects (e.g., parameters associated with the crack tip process). Nevertheless, it is only necessary to calibrate the model with a single crack growth rate under specified conditions (see [Figure 8](#)) and to choose an appropriate activation energy for the crack tip strain rate (this is actually equivalent to calibrating the model with CGR data at two temperatures), in order to accurately describe crack growth rate in sensitized Type 304 SS over temperatures ranging from 25 to 288 °C.

One of the persistent issues that is raised in debates on the basis of the CEFM concerns the role of the external environment in determining the crack growth rate. If the differential aeration hypothesis (DAH) is accepted as the basis for localized corrosion, including SCC, then the importance of the external environment is unequivocal. That the external environment is intimately involved has been demonstrated experimentally by detecting and measuring the coupling current that flows from the crack to the external surfaces where it is consumed by oxygen reduction.<sup>88,89</sup> Furthermore, unless the cathodic processes are confined to the crack, in which case the measured coupling current would be zero, and hence at odds with experiment,<sup>86</sup> the conservation of charge *requires* consideration of the external environment in any deterministic

description of crack growth. Finally, catalysis<sup>88</sup> and inhibition<sup>87</sup> of the oxygen reduction reaction on the external surface is found to increase and decrease the crack growth rate, respectively. In the case of inhibition, which was affected by depositing Zirconia on the external surfaces, the extent of inhibition was in agreement with that calculated by the CEFM by reducing the exchange current density for the oxygen electrode reaction by the amount indicated by electrochemical impedance spectroscopy measurements of the specific interfacial impedance using a fast redox couple  $[\text{Fe}(\text{CN})_6^{3-/4-}]$ .<sup>87</sup> These studies unequivocally demonstrate the importance, and possibly the dominance, of the processes occurring, on the external surfaces in determining the crack growth rate in sensitized Type 304 SS in high temperature aqueous systems.

The role of the external environment is further demonstrated by the calculated polarization data plotted in Figure 9.<sup>93,108</sup> Thus, it is seen that, at low temperatures (e.g., 50 °C), significant polarization is predicted to occur in the external environment (170 mV). As the temperature increases, the polarization in the external environment is predicted to decrease, but nevertheless remains significant at temperatures up to 250 °C. Even at higher temperatures, where the external polarization has been decreased to

small values, because of increased conductivity of the external environment and increased rate of oxygen reduction on the external surfaces, the external environment must still be considered because of the need for charge conservation. The temptation has been to assume that, in this case, the potential at the crack mouth can be equated to  $\phi_m = -E_{\text{corr}}$ , and hence to eliminate the need to consider the external environment altogether. However, this would be to assume that no potential gradient exists in the external environment, in which case no coupling current should be detected, again at odds with experiment,<sup>89</sup> leading to the prediction that SCC cannot occur. Finally, it is interesting to note that the decrease in the polarization in the external environment is predicted to be at the expense of an increase in the potential drop down the crack.

As noted elsewhere,<sup>90,104</sup> the CEFM predicts that the crack growth rate for given values of stress intensity, ECP, conductivity, etc. depends upon the crack length. This prediction is consistent with the available experimental data.<sup>19,88,105</sup> In discussing this topic, it is necessary to differentiate between the mechanical crack length (MCL), which is traditionally referred to as the 'crack length' in fracture studies, and the 'electrochemical crack length' (ECL), as noted previously.<sup>19,88,105</sup> The electrochemical

**Figure 9** The calculated effect of temperature on the pH of the external environment, the electrochemical potential at the crack tip,  $E_{\text{tip}}$ , the potential at the crack mouth,  $E_{\text{mouth}}$ , and on the potential in the external environment (ECP), during crack growth in Type 304 stainless steel in dilute sulfuric acid solution having an ambient temperature (25 °C) conductivity of  $0.27 \mu\text{S cm}^{-1}$  and a dissolved oxygen concentration of 200 ppb. The data were calculated using the CEFM after calibration at 288 °C and assuming a crack tip strain rate thermal activation energy of  $100 \text{ kJ mol}^{-1}$  (Congleton crack tip strain rate model).<sup>93</sup>

crack length is defined as the shortest path through the solution from the crack front, where the coupling current is generated, to the external surface, where the current is consumed. For a CT specimen, the MCL corresponds physically to the distance between the load line (for example) and the crack tip, and this distance increases as the crack grows through the specimen. On the other hand, because of the through thickness nature of a crack in a CT specimen, the ECL is constant and is essentially independent of the MCL. Furthermore, a CT geometry yields a distribution in ECL, depending upon where the current originates at the crack front. This dependence is such that the crack growth rate is highest at the crack edges (smallest ECL), but is lowest for the coupling current that originates from the crack front in the center of the specimen (largest ECL) by virtue of the dependence of crack growth rate on the electrochemical crack length.<sup>90,102,104</sup> This phenomenon is responsible for the generation of convex crack fronts, when the crack grows by SCC, in contrast to the concave crack front obtained for creep crack growth.<sup>105</sup>

Finally, we note that the CEFM is used extensively in various corrosion damage codes developed by Macdonald and coworkers (DAMAGE PREDICTOR, ALERT, REMAIN, FOCUS)<sup>19,23</sup> to predict stress corrosion cracking damage in BWR primary coolant circuits, as described below. To date, fourteen BWRs have been modeled and, where comparison is possible, the predicted damage is found to be in excellent agreement with that observed in the field.

### 2.39.6.3 Simplified Approach for Calculating Propagation Rates

It is well known from experiment that the rates of individual pit (crack) propagation as a function of time at constant environmental conditions can be approximated by a relatively simple function of time. Thus, for the case of pitting corrosion, the power function,

$$a = kt^m \quad [70]$$

has been suggested, where  $k$  and  $m$  are empirical constants.<sup>11,58,109</sup> Here,  $a$  is the characteristic pit size (e.g., pit depth or radius of the pit mouth). Published values of  $m$  are very often approximately equal to 1/3, 1/2, 2/3 or 1, but they can also vary over wider ranges.<sup>11,109–111</sup>

However, this dependence of  $a$  on  $t$  cannot be used directly in mathematical calculations for small times,

because of the nonphysical limit

$$V_s = \frac{da}{dt} = km t^{m-1} \rightarrow \infty, \text{ at } t \rightarrow 0 \text{ for } m < 1 \quad [71]$$

This is why, instead of eqn [70], the following interpolation equation for pit propagation rate,  $V_s$ , has been suggested<sup>91</sup>

$$V_s = \frac{da}{dt} = V_0(1 + t/t_0)^n \quad [72]$$

where  $n = m - 1$  and  $t_0$  are constants, and  $V_0$  is the initial, finite rate of pit propagation. Equation [72] yields  $V = V_0$  at  $t/t_0 \ll 0$  and  $V = V_0(t/t_0)^n$  at  $t \gg t_0$ .

Integration of eqn [72] with the boundary condition  $a = 0$  at  $t = 0$  yields

$$a = x_0[(1 + t/t_0)^m - 1] \quad [73]$$

where  $x_0 = t_0 V_0/m$ . For small times, as follows from eqn [73],  $a$  can be presented as the linear function of  $t$ ,  $a = V_0 t$  and for large times,  $a$  takes the form of eqn [70]. In many cases, the period of time over which the approximation

$$V(t)V_0 = \text{Constant} \quad [74]$$

is valid can be comparable with the observation time (or even with the service life of the system). The reason is that corrosion is, generally speaking, a slow process and under real, practical conditions, values of the critical pit depth of the system,  $x_{cr}$ , and typical service life,  $t_s$ , impose significant restrictions on the values of the initial and average corrosion current densities and, thus, on the potential and concentration drops that might be observed in a corrosion cavity.<sup>112</sup>

For constant external conditions, the dependence of cavity propagation rate as a function of the cavity depth,  $x$ , can be written in the form

$$V_s = \frac{da}{dt} = V_0 \varsigma(x) \quad [74]$$

where function  $\varsigma(x)$  satisfies the evident boundary condition  $\varsigma(x) \rightarrow 1$  at  $x \rightarrow 0$ . For the particular case when eqn [72] holds,  $\varsigma(x)$  can be expressed in the form:

$$\varsigma(x) = \frac{1}{(1 + x/x_0)^{(1-m)/m}} \quad [75]$$

where  $x_0 = v_0 t_0/m$ .

The general approach based on the numerical solution of the system of mass transfer equations does not present the depth of pit in the form of eqn [70] or [73]. As noted in Turnbull,<sup>58</sup> the mechanistically based models are complex to set up and, at the

present stage of development, are not user-friendly. For us, it is most important that the solution of the full system of mass transfer equations for the ensemble of pits is practically unrealistic for usual systems, from the point of view of the required computation time. One way to deal with this problem is to perform numerous calculations of pit propagation in advance and approximate the obtained results by eqns [70] or [73]. The other way is to try, after some simplification that does not significantly reduce the accuracy of calculations, to develop a model that can yield a cavity propagation law of the form of eqns [70] or [73], and that may even yield analytical expressions for parameters  $k$  and  $m$ . The principal concept in this simplification is that, if the rate of corrosion reaction depends explicitly only on the local potential and some surface concentrations of particular species (e.g.,  $\text{Cl}^-$  and  $\text{H}^+$ ), the pit growth rate depends only on the concentrations of those species that determine the value of electrostatic potential near the corroding surface.

Below, we will consider the example of such an approach for the simplest (but perhaps the most important, from the practical point of view) case of the corrosion of steels in neutral solutions. Thus, it has been suggested that, in the mathematical simulation of the corrosion of Fe in NaCl solutions, at least six species in the solution must be taken into the account.<sup>91</sup>

$$S_1 \equiv \text{Fe}^{2+}; S_2 \equiv \text{Fe}(\text{OH})^+; S_3 \equiv \text{Na}^+; S_4 \equiv \text{Cl}^-;$$

$$S_5 \equiv \text{H}^+; \text{ and } S_6 \equiv \text{OH}^-$$

These species include iron ions from the dissolution process, sodium and chloride ions (for example) that are commonly included to control the bulk conductivity, hydrogen and hydroxyl ions from the dissociation of water, and a metal hydrolysis product (for example). In the simplest case, the following homogeneous hydrolysis reactions are assumed to occur

with  $\text{Fe}(\text{OH})_2(\text{s})$  representing the precipitated hydrolysis product. Homogeneous reactions include hydrolysis processes and also precipitation processes. If the degree of supersaturation is sufficiently high, direct precipitation will occur in the solution itself; otherwise, precipitation will tend to occur on the walls preferentially. However, if an appropriate balance is obtained between the rate of production of the

**Figure 10** The concentration of species down a corroding cavity (crevice) in 0.1 M NaCl at 25 °C as functions of the quasipotential.

hydrolyzing species and the rate of precipitation, general saturation is expected to occur.<sup>60</sup>

We will assume that a single electrochemical reaction

occurs on the walls of the cavity.

Numerical solution of the corresponding boundary problem has been performed<sup>91</sup> by using the values of kinetic parameters from Sharland *et al.*<sup>78</sup> Figure 10 shows the concentrations profiles as a function of the quasipotential,  $q$ .<sup>68</sup> Please note that, for the case of a deep, one-dimensional cylindrical pit with passive walls or for a crevice with parallel passive sides,  $q = ix$ , where  $x$  is the distance down the cavity, and  $i$  is the current density in the crevice that is determined by the dissolution rate.<sup>91,112</sup> We can see that there are three species that dominate in the pit,  $\text{Fe}^{2+}$ ,  $\text{Cl}^-$ , and  $\text{Na}^+$ , and only these species determine the electrostatic field in the cavity.

Let us now assume in addition, that, the electro-dissolution reaction occurring in the cavity due to oxidation of the metal, can be described in terms of the Tafel equation as

$$\begin{aligned} i &= i_0 \exp \left\{ \frac{\alpha F (V_m - U_0 - \phi_s)}{RT} \right\} \\ &= i^* \exp \left\{ -\frac{\alpha F \phi_s}{RT} \right\} \end{aligned} \quad [80]$$

Here,  $i_0$  is the exchange current density,  $\alpha$  is the anodic transfer coefficient,  $V_m$  is the local electrode potential,  $U_0$  is the open-circuit potential (measured on the external surface remote from the pit),  $\phi_s$  is the electrostatic potential in the solution near the

electrode surface, all referred to a reference electrode at infinity, and  $i^* = i_0 \exp \{ \alpha F (V_m - U_0) / RT \}$  is the current density calculated in the absence of a potential drop in the cell ( $\phi_s = 0$  corresponding to the maximum possible current density on the electrode surface at the given potential of the metal).

Hence, if we only want to calculate the potential distribution and rate of corrosion in this system, we can approximate the complete system involving six species ( $\text{Fe}^{2+}$ ,  $\text{Fe}(\text{OH})^+$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{H}^+$  and  $\text{OH}^-$ ) by a reduced system involving only three species ( $\text{Fe}^{2+}$ ,  $\text{Na}^+$  and  $\text{Cl}^-$ ).

In this case, the solution of the mass transfer equations for this simplified system can be easily performed even in analytical form. In particular, if the polarization curve for reaction [79] can be described by Tafel's law [80] with the symmetry factor,  $\alpha$ , it was shown that the depth of one dimensional pit with passive walls can be described by eqn [73] with

$$m = \frac{\alpha + 1}{2\alpha + 1} \quad [81]$$

and

$$x_0 = 3FD_1 C_{\text{Cl}^-}^b / i^*, \quad V_0 = K_V i^*, \quad t_0 = mx_0 / V_0 \quad [82]$$

where  $D_1$  is the diffusion coefficient of  $\text{Fe}^{2+}$ , and  $C_{\text{Cl}^-}^b$  is the bulk concentration of chloride ions. Moreover, if  $\alpha = 1$  (typical value for corrosion of steels), eqn [81] yields  $m = 2/3$ .

If, for example,  $C_{\text{Cl}^-}^b = 0.6 \text{ M}$  (which corresponds approximately in the case of seawater),  $i^* = 10^{-4} \text{ A cm}^{-2}$  (which corresponds to an initial propagation rate,  $V_0$ , of  $\sim 1 \text{ mm year}^{-1}$ ) and  $D_1 = 0.72 \text{ cm}^2/\text{s}$ , eqn [82] yields  $x_0 \approx 12 \text{ cm}$ . Accordingly, if the critical depth of the pit penetration  $x_{\text{cr}}$  is of the order of 1 cm, as follows from eqns [74] and [75], it is possible to conclude that the pit will propagate at a constant rate because, when  $x_0$  is a large number  $\zeta(x)$  becomes equal to one. The physical reason for this uniform propagation is that the potential (and concentration) drops are very small in this system for the adopted values of dimensions, kinetic parameters, and environmental conditions. We can also state that the mere fact that hemispherical (or approximately hemispherical) pits exist can be explained by the insignificance of the potential drop in the corrosion cavity. Otherwise, the corrosion current density on the edge of the pit becomes higher than that on the bottom, and the pit will quickly assume a shallow ('saucer') form. This initial rate can be determined by using the experimentally measured polarization curves in the region of active dissolution, and can be calculated

for certain metals and alloys for different environmental conditions by using available software.<sup>71</sup>

However, it is also possible that pits can propagate with a constant rate, in spite of the fact that significant potential drops may exist down the cavity. In many cases, the rate of corrosion depends on the concentration of aggressive anions (e.g., chloride ions) near the metal surface. This dependence is usually approximated by the following relation<sup>11</sup>:

$$i = k_a C_{\text{As}}^\lambda \exp \left\{ \frac{\alpha F (V_m - U_0 - \phi_s)}{RT} \right\} \quad [83]$$

where  $C_{\text{As}}$  is the surface concentration of the aggressive anion,  $k_a$  is the rate constant for the reaction proceeding in the anodic direction, and  $\lambda$  is the effective kinetic order of the metal dissolution reaction with respect to the anion concentration. The value of  $\lambda$  is usually restricted to  $0 \leq \lambda \leq 1$ .<sup>11</sup> It was shown that, in this case, instead of eqn [81], we can use the alternate equation<sup>91,112</sup>

$$m = \frac{\alpha_{\text{eff}} + 1}{2\alpha_{\text{eff}} + 1} \quad [84]$$

where

$$\alpha_{\text{eff}} = \alpha - \lambda \quad [85]$$

It is clear that if  $\alpha \approx \lambda$ , we have  $m \approx 1$ , and the pit propagates with an approximately constant rate.

Generally speaking, under real, practical conditions, values of the critical pit depth of the system,  $x_{\text{cr}}$ , and typical service life,  $t_s$ , impose significant restrictions on the corrosion current densities (averaged and initial) and thus on the potential and concentration drops that might be observed in the corrosion cavity. Thus, if  $x_{\text{cr}}$  does not exceed the order of 1–10 mm, and if the order of  $t_s$  is not less than 1 year, initial corrosion current densities in real, open pits cannot exceed values of  $10^{-4}$  to  $10^{-3} \text{ A cm}^{-2}$ , with the understanding that the polarization curve (corrosion current density versus potential) and the surface concentrations of the species do not change as the pit propagates.<sup>112</sup> Simple analytical expressions for predicting the potential and concentration drops in open corrosion cavities and for predicting cavity propagation rate in systems containing uni- and bivalent anions in stagnant electrolytes under well mixed, external conditions have been obtained.<sup>112</sup>

After the transition of a pit into a crack or into a corrosion fatigue crevice, the total rate of corrosion cavity propagation,  $V_s$ , cannot be described simply by Faraday's law, but also has to contain mechanical

and, in the general case, some additional environmental component (e.g., hydrogen embrittlement component). It would be natural to assume that  $V_s$  is a known function of the environmental (concentration of species near metal surface, temperature) and mechanical parameters (stress), and so on. The explicit forms of these dependences are discussed in the corresponding chapters of this book. Here, only the most general relations will be discussed.

**Figure 8** clearly shows that at low corrosion potential, the crack propagation rate does not depend on  $E_{\text{corr}}$ , that is,  $V_s$  reduces to the mechanical (creep) component. It is also clear that at high values of  $E_{\text{corr}}$ , crack propagation rate does not depend on creep rate and is described by an exponential dependence of the Tafel type. Accordingly, in the first approximation, we can present  $V_s$  as the sum of two contributions

$$V = V_{\text{env}} + V_{\text{mech}} \quad [86]$$

where  $V_{\text{env}}$  is the environmental/electrochemical component, which is often determined by Faraday's law, and  $V_{\text{mech}}$  is the mechanical component (crack advance associated with mechanical fatigue/creep). Of course, in some cases, the synergistic interaction of mechanical and environmental attack can play a role and a simple summation, as expressed by [eqn \[86\]](#), may not be appropriate.<sup>113</sup>

A review of many models for describing environment-induced cracking based directly or indirectly on anodic reaction processes or on hydrogen embrittlement can be found.<sup>114,115</sup> Thus, in accordance with the slip-dissolution model, the average crack growth velocity will be given by

$$V_{\text{env}} = K_v i_{\text{corr}}^0 \Gamma \quad [87]$$

where  $i_{\text{corr}}^0$  is the current density on the bare surface, and  $\Gamma$  is the ratio of the bare surface of the crack tip to the total geometrical surface. It can be shown that

$$\Gamma = \frac{t_0''}{(1-n)\varepsilon_f''} (\dot{\varepsilon}_{\text{ct}})^n \quad [88]$$

where  $\varepsilon_v$  is the fracture strain of the passive film at the crack apex,  $\dot{\varepsilon}_{\text{ct}}$  is the crack tip strain rate, and  $t_0$  and  $n$  are material constants. It is evident that  $\Gamma \leq 1$ . In turn, the expressions for  $\dot{\varepsilon}_{\text{ct}}$  can be found as described in Engelhardt *et al.*,<sup>92</sup> Turnbull,<sup>114</sup> and Peng *et al.*<sup>116</sup>

In the case of corrosion fatigue, the crack growth rate is usually expressed in terms of the increment of crack growth during each fatigue cycle,  $da/dN = V_s/f$  (where  $f$  is the frequency of the applied stress). Very often, this rate follows the well known power-law

relationship (Paris' law)

$$\frac{da}{dN} = C(\Delta K)^n \quad [89]$$

for both fatigue (no corrosion) and corrosion fatigue. Here,  $\Delta K$  is the stress intensity factor range and  $C$  and  $n$  are empirical parameters that depend, in the general case, on environmental conditions. While the dependencies of the Paris equation parameters on environmental conditions is well recognized through numerous experimental studies, few of the models for corrosion fatigue developed to date incorporate environmental effects in an explicit, mechanistic manner. This is another example of where the underlying (mechanical) theory fails to account for the experimental data, and the resultant models fail to meet the requirements of determinism.

Until now, it has been tacitly assumed that the rate of pit (crack) propagation is unequivocally determined by its depth and by the external conditions, that is, there is no distribution in cavity propagation rate for pit cavities of equal depth. However, as noted above, a distribution in pit (crack) propagation rate might be observed in practical systems because of underlying distributions in system parameters that affect the growth rate. Usually, such problems are considered in the following way. In the case of pitting corrosion, it is assumed that the pit depth is described by [eqn \[70\]](#) with distributed parameters  $k$  and  $m$ .<sup>117</sup> However, in Turnbull *et al.*,<sup>118</sup> it is assumed for simplicity, that only parameter  $k$  is normally distributed; parameter  $m$  is assumed to be fixed, and its value is obtained by fitting the model to the experimental data. In contrast, in Harlow and Wei,<sup>3</sup> it is assumed that the pit maintained a hemispherical geometry and grew at a constant volumetric rate. From this fact, it immediately follows that  $m = \text{const} = 1/3$ . On the other hand, it was assumed that parameter  $k$  is described by a Weibull distribution.

Analogously, in Turnbull *et al.*,<sup>118</sup> for the case of SCC, the crack propagation rate was assumed to be given by

$$\frac{da}{dt} = C\sigma^p a^q \quad [90]$$

where  $\sigma$  is the applied stress. It was assumed that parameters  $p$  and  $q$  are fixed and were determined by fitting [eqn \[90\]](#) to the experimental data, but parameter  $C$  was assumed to be normally distributed. Additionally, for example, in Harlow and Wei,<sup>3</sup> for the case of corrosion fatigue, it was assumed that crack propagation is described by [eqn \[89\]](#) with

fixed crack growth exponent,  $n$ , and distributed parameter  $C$ .

Of course, few of the models that are discussed in this section are ‘deterministic’ in nature, although they are certainly ‘mechanistic’ in form. Determinism is readily introduced by first identifying the relevant natural laws and then ensuring that the predictions are constrained by these laws. In many cases, this would be most effectively done by introducing the models, which for the most part, describe the ‘anodic’ part of the corrosion cell, into a ‘coupled environment’ framework to impose the conservation of charge. This again illustrates the important difference between ‘mechanistic’ and ‘deterministic’ models, with only the latter constraining the output (‘predictions’) to those that are ‘physically real’ (i.e., that are consistent with scientific knowledge).

### 2.39.7 Rate of Pit Repassivation and Transition of Pits into Cracks

As noted above, we assume that the repassivation process obeys a first-order decay law

$$R_a(x, t) = -\gamma f_a(x, t) \quad [91]$$

where  $\gamma$  is the delayed repassivation (‘death’) constant (i.e., the rate constant for repassivation of stable pits), and  $f_a$  is the differential damage function for active pits. The repassivation constant,  $\gamma$ , is, in general, expected to be a function of the external conditions, including the corrosion potential, temperature, and electrolyte composition. Generally speaking,  $\gamma$  is also expected to be a function of the depth of the pit,  $x$ , because the local potential in the solution at the cavity surface depends on the IR potential drop in the cavity, that is,  $\gamma$  might be a function of both the spatial coordinates and time. Of course, if the potential and concentration drops inside the corrosion cavity are insignificant during pit propagation, it is possible to neglect changes in  $\gamma$  (see above). However, the value of this constant still depends on the external conditions, such as potential, pH, and concentration of aggressive species in the bulk electrolyte. Finally, active pits may no longer be viable if the potential,  $E$ , at the pit internal surface is less than the repassivation value,  $E_{rp}$ . Accordingly, if the value of  $E_{rp}$  is reached at some pit depth,  $x_{rp}$ , active pits passivate and cannot penetrate further into the metal. The value of repassivation potential  $E_{rp}$  is a function of the metal potential and surface concentrations at the pit tip. It can be

calculated, for example, by using methodology described in Anderko *et al.*<sup>119</sup>

Regarding the transition of a pit into a crack, we assume that a pit immediately transforms into a crack if its depth exceeds some critical value  $x_{tc}$ . As of now, the most widely accepted set of criteria for the transition of a pit into crack are the Kondo criteria.<sup>120</sup> According to these criteria, two conditions must be satisfied for crack nucleation to take place from a pit, namely,

$$K_I > K_{ISCC}(\text{for SCC}) \text{ or } \Delta K > \Delta K_{th}(\text{for CF}) \quad [92]$$

and

$$V_{crack} > V_{pit} \quad [93]$$

Here,  $K_I$  and  $K_{ISCC}$  are the stress intensity factor and critical stress intensity factor for propagation of a stress corrosion crack, respectively;  $\Delta K$  is the stress intensity factor range, and  $\Delta K_{th}$  is the threshold stress intensity factor range for fatigue crack propagation, respectively.

The first requirement defines the mechanical (fracture mechanics) condition that must be met for the prevailing stress and geometry, while the second simply says that the nucleating crack must be able to ‘outrun’ the pit.

It is important to note the following circumstance. At high values of corrosion potential,  $E_{corr}$ , the environmental component of crack propagation rate,  $V_{env}$ , could be much higher than the mechanical component,  $V_{mech}$  (see [Figure 8](#)). Accordingly, the crack propagation rate,  $V_{crack}$  will practically coincide with its environmental part,  $V_{env}$ .

In accordance with the slip dissolution model, the crevice tip is partially blocked by the passive film. Accordingly, for a given set of tip conditions (metal potential, pH, etc.),  $V_{env}$  must be smaller than that corresponding to the pit propagation rate,  $V_{pit}$ , with the tip surface being bare (see [eqn \[87\]](#)). This means that, under these conditions, the transition from a pit into a crack occurs if (1) the depth of the pit exceeds some critical length,  $x_{mech}$  (where  $K_I \geq K_{ISCC}$  or  $\Delta K_I \geq \Delta K_{I,th}$ ); and (2) the pit is passivated (when  $V_{pit}$  is very small). Thus, this latter criterion suggests that cracks will nucleate only from ‘dead’ pits. This example shows how important repassivation phenomena may be for predicting corrosion damage.

### 2.39.8 Statistical Properties of the Damage Function

There exists a close correspondence between damage function analysis (DFA), which has been described at some length above, and extreme value statistics (EVS). The latter technique has been used extensively to extrapolate damage (maximum pit or crack depth) from small samples in the laboratory to larger area samples in the field. Furthermore, DFA provides a means of calculating the central and scale parameters and their time-dependencies in EVS from first principles, and hence represents a unification of the two prediction philosophies.

From a statistical point of view, all distributed properties of the system are completely determined by the cumulative distribution function (CDF),  $\Phi(x)$ . By definition,  $\Phi(x)$  is the probability that the depth of a randomly selected pit (crack) is  $\leq x$ . We postulate that the pit distribution on the metal surface is uniform. Accordingly, the total number of nucleated pits in the entire system is  $SN(t)$ , where  $S$  is the area of the system and, from the definition of the integral damage function,  $F$ , the number of pits that have the depth  $\geq x$ , is  $S[N(t) - F(x, t)]$ . Accordingly, from the definition of probability, we have

$$\Phi(x, t) = \frac{S[N(t) - F(x, t)]}{SN(t)} = 1 - \frac{F(x, t)}{N(t)} \quad [94]$$

We see that the CDF for a given observation time,  $\Phi(x, t)$ , can be predicted if we know (can calculate) the integral damage function of the system (note that the number of nucleated, stable pits,  $N(t)$  simply equals  $F(0, t)$ ). This relationship can be regarded as being the bridge between the statistical and deterministic approaches for estimating the accumulation of localized corrosion damage on a surface.

As noted above, from the practical point of view, the most important value for characterizing corrosion damage is the failure probability,  $P_f$ , of the system. By definition,  $P_f$  is the probability that at least one corrosion event in any form (pit, crevice, stress corrosion crack, or fatigue crack) reaches a depth,  $x$ , at a given observation time,  $t$ , where  $x$ , in this case, is the critical dimension. It can be shown<sup>14</sup> that

$$P_f(x, t) = 1 - \exp\{-SF(x, t)\} \quad [95]$$

Equation [95] allows us to calculate the probability of failure if the integral damage function,  $F$ , is known. The latter function can be found as a solution of eqn [4]. However, here we will reject the equal velocities for all

pits with a given depth assumption that was adopted previously (see eqn [9]). Thus, it is well known that the morphology of pits on any given surface can vary significantly, with some shapes favoring more rapid mass and charge transfer, and hence, a greater propagation rate.<sup>121</sup> In addition, some pits will initiate at metallurgical features that may favor more rapid propagation, for example, at MnS inclusion.<sup>121</sup> The distribution in pit propagation rate might also be explained, for example, by the spatial distribution in electrochemical activity of the anodic and cathodic sites on the corroding surface.<sup>122</sup>

Here, we will assume that the pits that propagate with initial rate  $V_0$  are nucleated in accordance with the equation.

$$n(t) = \int_0^\infty \lambda(t, V_0) dV_0 \quad [96]$$

The function  $\lambda(t, V_0)$  yields the number of pits (per square centimeters) that have initial propagation rates between  $V_0$  and  $V_0 + dV_0$  and that nucleate in the period of time between  $t$  and  $t + dt$ . Further propagation of the pits takes place in accordance with eqn [74]. It can be shown that, in this case, the expression for the flux of active pits can be expressed in general form as<sup>123</sup>

$$j_a(x, t) = \int_0^\infty \exp[-\gamma g(x)/V_0] \lambda[t - g(x)/V_0, V_0] dV_0 \quad [97]$$

where

$$g(x) = \int_0^x \frac{dx'}{\zeta(x')} \quad [98]$$

(compare with eqn [9]). Accordingly, the expressions for the differential damage functions for active and passive pits and the integral damage function have the following forms<sup>123</sup> as solutions of eqn [4]

$$f_a = \int_0^\infty \frac{\exp[-\gamma g(x)/V_0] \lambda[t - g(x)/V_0, V_0]}{V_0 \zeta(x)} dV_0 \quad [99]$$

and

$$f_p = \int_0^\infty \frac{\gamma \exp[-\gamma g(x)/V_0] A[t - g(x)/V_0, V_0]}{V_0 \zeta(x)} dV_0 \quad [100]$$

Furthermore, for the case of pitting corrosion, the total integral damage function,  $F$ , is<sup>123</sup>

$$F = \int_0^{\infty} \exp[-\gamma g(x)/V_0] A[t - g(x)/V_0, V_0] dV_0 \quad [101]$$

where  $A(t, V_0) = \int_0^t \lambda(t', V_0) dt'$  yields the number of pits (per square centimeters) that have initial propagation rates between  $V_0$  and  $V_0 + dV_0$  and nucleate in the period of time between 0 and  $t$ .  $F$  is the sum of the integral damage functions for active and passive pits for the given case.

Let us assume that the distribution in initial pit propagation rate does not depend on time, that is,

$$\lambda(t, V_0) = n(t)\psi(V_0) \quad [102]$$

To move further, we must assume a distribution function,  $\psi(V_0)$ , for the pit growth rate, in order to account for those factors that result in a distribution in growth rate that is not captured by the (present) deterministic models. For our purposes, it is most convenient to approximate  $\psi(V_0)$  by Laplace's distribution function

$$\psi(V_0) = \frac{\exp(-|V_0 - \bar{V}_0|/\beta)}{2\beta} \quad [103]$$

where  $\bar{V}_0$  is the mean initial pit propagation rate and  $\sigma^2 = 2\beta^2$  is the dispersion.

If eqn [102] holds, we have, for the integral damage function and the cumulative damage function, the following expressions

$$F(x, t) = \int_0^{\infty} N[t - g(x)/V_0] \exp[-\gamma g(x)/V_0] \psi(V_0) dV_0 \quad [104]$$

and

$$\Phi(x, t) = 1 - \int_0^{\infty} N[t - g(x)/V_0] \exp[-\gamma g(x)/V_0] \psi(V_0) dV_0 / N(t) \quad [105]$$

respectively. In particular, for the case of instantaneous nucleation, we have

$$\Phi(x, t) = 1 - \int_{x/t}^{\infty} \exp[-\gamma g(x)/V_0] \psi(V_0) dV_0 \quad [106]$$

As has been shown experimentally, in many practical cases, the asymptotic behavior (for large values of  $x$ ) of the CDF can be described by the exponential relationship<sup>58,121</sup>

$$\Phi(x, t) = 1 - \exp[-(x - u)/\alpha] \quad [107]$$

where  $u$  is the central parameter (the most frequent value), and  $\alpha$  is the scale parameter, which defines the width of the distribution. Accordingly, as follows from eqn [107], the extreme value distribution (EVD),  $\psi(x, t)$  (the probability that the largest value of pit depth  $\leq x$ ), is described by a double exponent (Gumbel Type I extreme value distribution) in the form<sup>58</sup>:

$$\Psi(x, t) = 1 - P_f = \exp[-\exp(-y)] \quad [108]$$

where

$$y = (x - b)/\alpha \quad [109]$$

and  $b = u + \alpha \ln(SN)$ .

Numerical calculation<sup>14</sup> shows that the dependencies of  $\ln(1 - \text{CDF})$  on pit depth,  $x$ , can be approximated by straight lines, at least for sufficiently large values of  $x$ , and therefore provide a theoretical basis for applying the Type I extreme value distributions to real corrosion systems. In some cases, parameters  $\alpha$  and  $b$  can be expressed in analytical form. Thus, for the case of instantaneous nucleation and constant pit propagation rate, these parameters can be presented in the form<sup>14</sup>:

$$\alpha = \frac{\beta t}{1 + \gamma \beta t / \bar{V}_0} \quad \text{and} \quad b = \frac{[\bar{V}_0 + \beta L n(0.5 S N_0)] t}{1 + \gamma \beta t / \bar{V}_0} \quad [110]$$

We see that, for small values of  $t$ , the parameters  $\alpha$  and  $b$  can be described by  $\alpha = \beta t$  and  $b = [\bar{V}_0 + \beta L n(0.5 S N_0)] t$ , that is, they are proportional to time. Such dependencies were actually observed, for example, for the case of the pitting corrosion of manganese steel in CO<sub>2</sub>-acidified seawater.<sup>122</sup> On the other hand, for large observation times, the parameters  $\alpha$  and  $b$  approach the following limits

$$\alpha = \bar{V}_0 / \gamma \quad \text{and} \quad b = [\bar{V}_0 + \beta L n(0.5 S N_0)] t \bar{V}_0 / \gamma \quad [111]$$

that are independent of time. This fact can be regarded as being physically evident, because at sufficiently large times, all pits become passive (the damage function becomes 'frozen'), and further propagation of damage cannot occur, provided that  $\gamma > 0$ . This conclusion concerning the achievement of limiting pitting depth also follows from a formal statistical treatment of experimental data for underground carbon steel pipelines.<sup>11</sup> The 'freezing' of damage functions can also be seen in the propagation of corrosion damage on aluminum in tap water.<sup>10</sup>

Equation [110] with eqn [108] can be used for calculating the probability of the failure of a system. Unfortunately, very often it can be the case that not

all, or even none, of the kinetic parameters that determine the pit (crack) nucleation rate, pit propagation rate, and pit repassivation rate, are known. However, unknown parameters are determined by comparing the results of analytical or numerical calculations of the depths of the deepest pits (cracks) with the corresponding experimentally observed values for short-term experiments. After determining values for the unknown parameters, the depths of the deepest pit (crevice) for the total system (i.e., for the system with arbitrary surface area) for long-term exposure are predicted.

Usually therefore, in the case when none of the kinetic parameters are known, the following expression, based on the Gumbel type-I distribution is used for predicting perforation probability in the large systems with the total area,  $S$ , by using the results of measurements of the depth of the deepest pits on the series coupons with area,  $s$ <sup>124</sup>

$$P_f = 1 - \exp\{-\exp[-(d - u + \alpha \ln(S/s))/\alpha]\} \quad [112]$$

where  $d$  is the thickness of the wall.

For predicting probability of failure in long-term experiments by using the results of measurements in short-term experiments, it is necessary to assume some functional dependence of the location parameter,  $u$ , and scale parameters,  $\alpha$ , on time. For the case when eqn [110] is valid, these parameters are described by hyperbolic relations of the form

$$u = \frac{a_1 t}{1 + a_2 t}, \quad \alpha = a_3 u \quad [113]$$

where,  $a_1$ ,  $a_2$ , and  $a_3$  are unknown parameters that must be fitted by using the short term experiments. The procedure of such fitting by using the maximum likelihood method is described in Laycock *et al.*<sup>125</sup>

Figure 11 illustrates the applicability of the hyperbolic dependencies for predicting the results of experiments measuring the depth of the deepest pits in the corrosion of aluminum Alloy 2S-O in Kingston tap water.<sup>10</sup> The mean depth of the deepest corrosion event,  $X_m$ , and standard deviation of this value,  $\sigma$ , can be calculated by using the following relations<sup>125</sup>:

$$X_m = b + \alpha[E + \ln(S/s)] \quad \text{and} \quad \sigma = \pi\alpha/\sqrt{6} \quad [114]$$

We see that applicability of the hyperbolic functions can be considered as being very satisfactory. Note that only the data for  $t = 1$  week and 1 month were used for calibration and hence, for prediction over a period of up to 1 year, providing accurate extrapolation over a range of 12 times that of the calibration range.

However, the typical time-relations that are usually used for estimating the location and scale parameters in extreme value distributions are of the power law type:

$$b = a_1 t^{a_2}, \quad \alpha = a_3 b \quad [115]$$

or logarithmic:

$$b = a_1 \log(t) + a_2, \quad \alpha = a_3 b \quad [116]$$

Figure 12 shows that application of the power law functions for fitting experimental data to the short

**Figure 11** The mean depth of the deepest pit as a function of time. Fitting to experimental data (black circles) has been performed by using the hyperbolic dependencies [113].

**Figure 12** Fitting to experimental data (black circles) has been performed by using power law dependencies [114].

term experiments yields results that are not as good as application of hyperbolic law, at least for the considered experimental data. This happens, because the power law [115] does not take into account the repassivation of pits that plays a substantial role in determining the results of Aziz's experiments.

From the above, it is evident that the application of the logarithmic law yields much more acceptable results than does the application of the power law (Figure 13). However, at present, there is no physical model that could explain a logarithmic law of pit growth. In reality, if we assume that the growth law of individual pits can be described by a logarithmic function, it can be easily shown that the rate of the pit growth must decrease in accordance with the exponential law ( $da/dt \sim \exp(-\zeta a)$ ). This dependence is substantially stronger than the maximum possible decrease of the rate of open pit growth under diffusion control when  $da/dt \sim 1/a$ . Accordingly, it might be suggested that the logarithmic dependence of pit growth is formally introduced for effectively describing pit propagation in the presence of repassivation phenomena.

A generalization of the hyperbolic function [113] in the form

$$b = \frac{a_1 t^{a_4}}{1 + a_2 t^{a_4}}, \quad \alpha = a_3 b \quad [117]$$

appears to offer some advantages. The principal advantage of the general hyperbolic dependence [117] is that it coincides with the power law at short times and yields the accurate transition:  $u, \alpha \rightarrow \text{constant}$  as  $t \rightarrow \infty$  as it must, due to the repassivation. It is interesting to note that calculation

**Figure 13** Fitting to experimental data (black circles) has been performed by using logarithmic dependencies [116].

shows that the parameter  $a_4 = 1.0093 \approx 1$ , that is, fitting by using the general hyperbolic dependencies yields, for the given case, practically the same results as the simple hyperbolic dependencies.

### 2.39.9 Monte Carlo Simulation

The existence of deterministic models to describe nucleation, propagation, and repassivation of localized corrosion processes allows us to replace the current DFA, which reduces to the direct solution of the balance eqns [2], with an alternative approach – Monte Carlo simulation of corrosion damage. However, it is worthwhile to develop this alternative

approach for describing corrosion damage for the following reasons. It is important to note that, frequently, under real conditions, only a few pits (or cracks), or sometimes only a single pit (or crack), may be alive (propagating) on the corroding metal surface (see the upper extremes in [Figure 1](#)). In this case, the differential equations for the damage function, which are equivalent to a balance equation for particles in discontinuous media, lose their strict physical meaning.

The main idea of the Monte Carlo method is to keep track of each stable pit (or crack) that nucleates, propagates and repassivates on the metal surface. A great advantage of this method lies in the fact that it allows us to take into account the interactions between particular individual pits (cracks) in an explicit manner. By doing so, it becomes possible to reduce the number of unknown parameters that describe the interaction between individual pits (cracks). Preliminary calculation shows that both approaches (DFA and Monte Carlo) yield the same results, if the same physical assumptions are made for describing the propagation of corrosion damage. At this point, it is important to note that, in the Monte Carlo method described here, the stages in the life of an individual pit or crack are described deterministically (i.e., in terms of models whose predictions are constrained by the natural laws), while the ensemble of pits is described statistically in terms of a Monte Carlo algorithm. Below, the current version of the deterministic Monte Carlo simulation (DMCS) algorithm that has been developed for predicting the accumulation of localized corrosion damage will be briefly described.

Let us denote by  $N_0$  the total number (not per square centimeters) of stable pits that can nucleate on a metal surface having a total area of  $S$ . We number these pits by the index  $k = 1, 2, \dots, N_0$ , and we will track each of these pits individually. Initially, we suggest that there are no stable pits on the metal surface. We proceed by calculating the probability that a pit will nucleate in stable form during the time step  $dt$  as

$$P_{\text{nuc}} = \frac{N(t+dt) - N(t)}{N_0 - N(t)} \quad [118]$$

where,  $N(t)$  is the number of stable pits that nucleate within the time interval between 0 and  $t$ . (Note that  $P_{\text{nuc}}$  is defined as a ratio of the number of pits that nucleate in the time interval between  $t$  and  $t+dt$  to the number of available remaining sites at moment  $t$ ).

For each pit,  $k$ , that has not yet been born, we generate a random number  $0 \leq G_k \leq 1$ . If  $G_k \leq P_{\text{nuc}}$ , a pit is proclaimed to have been born with a depth of penetration  $x = 0$ ; otherwise, it is considered not to have been born and will be interrogated in the following step. In the case of instantaneous nucleation, all pits in the amount of  $N_0$  are born during the first time step. In the more general 'progressive nucleation' case, the function  $N(t)$  can be calculated by using, for example, the PDM, as noted above. The Cartesian coordinates of the centers of the nucleated pits,  $X_k$  and  $Y_k$ , are also established by using the random number generator, but this will be modified in the future to correspond to particular metallurgical, microstructural, and microchemical features on the surface (e.g., emergent precipitates or second phase particles) that may not be randomly distributed (e.g.,  $\text{Cr}_{23}\text{C}_7$  precipitates on emergent grain boundaries in stainless steels). This innovation will introduce, surface structural factors for the first time, in the deterministic prediction of localized corrosion damage. Practically, if the surface is rectangular with area  $a \times b$ , the Cartesian coordinates  $X_k$  and  $Y_k$  are declared to be  $X_k = G_m$  and  $Y_k = G_b$ , where  $0 \leq G \leq 1$  is a random number. If the surface is not rectangular, we insert the surface into a sufficiently large rectangle so that all points on the actual surface are included, and then repeat the described procedure. However, in this case, we declare  $X_k$  and  $Y_k$  as a center of a newly-born pit only if the point  $(X_k, Y_k)$  lies inside the actual surface. Otherwise, the procedure is repeated until success is achieved, that is, until  $(X_k, Y_k)$  lie inside the actual surface.

At each time step, the depth of the  $j$ -th stable, living pit,  $a_j$ , is calculated sequentially by using Faraday's law

$$a_j(t+dt) = a_j(t) + K_V i_j(t) dt \quad [119]$$

We assume that  $i_j$  is described by Tafel's law for the active metal dissolution current density as a function of potential, that is,

$$i_j = i_0 \exp\left(-\frac{\alpha F \Delta\phi_j}{RT}\right) \text{ at } \Delta\phi_j < \Delta\phi_{\text{cr}} \text{ and} \quad [120]$$

$$i_j = 0 \text{ at } \Delta\phi_j \geq \Delta\phi_{\text{cr}}$$

where  $\Delta\phi_j$  is the averaged potential drop on the active surface (relative to a point that is remote from the hemispherical pit of index  $j$ ),  $\alpha$  is the transfer coefficient of the metal dissolution reaction,  $i_0$  is the corrosion current density at the corrosion potential,  $T$  is the Kelvin temperature,  $F$  is Faraday's constant, and  $R$  is

the gas constant. The physical meaning of the value  $\Delta\phi_{cr}$  is as follows. We can assume that the pit should continue to grow (be alive) if the metal potential at the bottom of the pit,  $E$ , is larger than the repassivation potential,  $E_{rp}$ , that is, at  $E = E_{corr} - \Delta\phi_j > E_{rp}$  or at  $\Delta\phi_j < E_{corr} - E_{rp}$ . In other words  $\Delta\phi_{cr} = E_{corr} - E_{rp}$  is the difference between corrosion and repassivation potentials. Of course, it is assumed that  $E_{corr} > V_{crit}$ , which in turn is greater than  $E_{rp}$ , otherwise pitting corrosion cannot be initiated.

It can be shown<sup>126</sup> that the average potential drop on the active surface of a hemispherical pit (relative to a point far away from it),  $\Delta\phi_j$ , can be estimated by the following relation

$$\Delta\phi_j = \frac{ba_j i_j}{\kappa} + \sum_{k \neq j} \frac{i_k a_k^2}{\kappa d_k} \quad [121]$$

Here, the index  $k$  denotes the pits on the surface (the pit of interest is denoted by the index  $j$ ),  $a_k$  is the radius of the hemispherical pit,  $i_k$  is the average current density inside the pit,  $\kappa$  is the conductivity, and  $b \approx 2.1$  is a constant. Equation [121] can be obtained as an approximate solution of Laplace's equation for the electrical potential for the ensemble of hemispherical pits embedded in a plane under the condition that pits are far apart, that is, when the contribution of each pit can be considered independently. Noting that  $\Delta\phi_j$  corresponds to the potential drop from some point within the pit and a remote point on the external surface, the first term in eqn [121] describes the contribution of the central pit to the total potential drop; this contribution can be found, for example, by using the method described in Pistorius and Burstein.<sup>32</sup> The second term describes the contribution of all other pits on the corroding surface.<sup>50</sup>

Accordingly,  $i_j$  is calculated by using eqn [121], where  $\Delta\phi_j$  is determined by a numerical solution of the equation

$$\Delta\phi_j = \frac{ba_j i_0}{\kappa} \exp\left(-\frac{\alpha F \Delta\phi_j}{RT}\right) + \sum_{k \neq j} \frac{i_0 a_k^2}{\kappa} \exp\left(-\frac{\alpha F \Delta\phi_k}{RT}\right) \quad [122]$$

By solving this equation, we assume that all  $\Delta\phi_k$  in the second term on the right-hand side of eqn [122] are known and are equal to their previous (in the iteration sense) values.

After each time step, the repassivated (dead) pits are excluded from the population of actively growing

pits. A pit is considered dead if  $\Delta\phi_j > \Delta\phi_{cr}$ . In addition, if two pits touch each other, that is, if

$$d_{ij} \leq a_i + a_j \quad [123]$$

where  $d_{ij}$  is the distance between the centers of the  $i$ th and  $j$ th pits, the smallest pit is declared repassivated (dead). A more correct assumption might be that, instead of two touching hemispherical pits, we have a single ellipsoidal pit with the depth of the deepest pit and a dimension obtained, for example, from the condition  $\pi a^2 = \pi a_i^2 + \pi a_j^2$ . Also, the entities that encroach on one another are the 'hemispheres of influence' (HOI), such that the pits begin to compete for the same resources (oxygen reduction). However, such an approach would substantially complicate the problem, but these factors will eventually be included in the analysis. To justify the adopted simplification, we note that the total area occupied by the active pits,  $S_a$ , must be much smaller than the area of the sample,  $S$ , in order to sustain differential aeration. Accordingly, overlap of the pits must be a relatively rare event. Moreover, our simplification can only decrease the value of  $\Delta\phi_j$  for any given pit  $j$ . Thus, if interactions between pits were substantial in the corrosion process, the conclusion would be all the more true than without the simplification.

In addition, we consider the probability that pits can repassivate accidentally (by chance). It is assumed that the probability of a pit repassivating during each time step is proportional to the magnitude of this step, that is,  $P_\gamma = \gamma dt$ , where  $\gamma$  is the delayed repassivation constant. Practically, for the  $j$ th living pit in each time step, we generate the random number  $0 \leq G \leq 1$ . If  $G \leq P_\gamma$ , the pit is declared to be dead (passivated) and is excluded from the further consideration; otherwise, the pit is considered to be alive on entering the next time step. We see that our Monte Carlo simulation method describes all three stages of the pit propagation damage – nucleation, propagation, and repassivation of stable pits.

**Table 2** Parameter values for model calculations

$i_0$	$1.5 \times 10^{-2} \text{ A cm}^{-2}$
$K_v$	$3.44 \times 10^{-5} \text{ cm}^3 \text{ C}^{-1}$
$\alpha$	1
$\kappa$	$0.3 \times 10^{-3} \Omega^{-1} \text{ cm}^{-1}$
$\Delta\phi_{cr}$	200 mV
$T$	25 °C
$\tau$	3 days
$a$	3.65 days
$b$	1
$\gamma$	0.066 day <sup>-1</sup>

**Figure 14** The mean depth of the deepest pit as a function of time. Experimental data are taken from Aziz<sup>10</sup> and are for aluminum alloy Alcan 2S-O in Kingston, Ontario tap water. Note that no calibration was performed on short term data, as was the case for Figure 11.

As an example of the application of this Monte Carlo simulation method within DFA, we consider again, the corrosion of aluminum alloy Alcan 2S-O in Kingston, Ontario tap water.<sup>10</sup> In this paper, for the purpose of numerically simulating the accumulation of pitting damage on the alloy surface, we will assume the values of various model parameters that are shown in Table 2. The parameters for the PDM ( $\tau$ ,  $a$ , and  $b$ ) were chosen somewhat arbitrarily. The aim was only to ensure that, by the end of two weeks, practically all stable pits had nucleated, as indicated by the experimental data.<sup>10</sup> The value of  $K_V$  corresponds to that for aluminum and the value of  $\kappa$  corresponds to that typically assumed for tap water. The value for the delayed repassivation constant,  $\gamma$ , was chosen to ensure that, by the end of 2 months, the bulk of the pits represented by the bell-shaped curve have ceased to grow (see Figure 1). The value of  $\alpha$  has been chosen as being typical for metal dissolution, and only the value of  $i_0$  has been fitted to the experimentally measured values of maximum pit depth at  $t = 1$  week after metal exposure.<sup>10</sup> Finally, the sample is considered to be rectangular with the dimensions  $7 \times 18$  cm and  $N_0 = 450$ .<sup>10</sup>

Figure 14 shows a comparison of results of the Monte Carlo simulation with experimental data.<sup>10</sup> For a given observation time,  $t$ , we perform  $M$  simulations as described above and, accordingly, receive  $M$  values  $x_1^*(t)$ ,  $x_2^*(t)$ ,  $\dots$ ,  $x_M^*(t)$  for the depth of the deepest pits. After that, we calculate the average (mean) value of the depth of the deepest pit as

**Figure 15** The mean depth of the deepest pit as a function of time for different conductivities of the electrolyte for aluminum alloy Alcan 2S-O in Kingston, Ontario tap water. Reproduced from Aziz, P. M. *Corrosion* 1956, 12, 35–46.

$$X_{av}(t) = \frac{1}{M} \sum_{m=1}^M x_m^*(t) \quad [124]$$

and the standard deviation as

$$\sigma(t) = \sqrt{\frac{1}{M-1} \sum_{m=1}^M (X_{av}(t) - x_m^*(t))^2} \quad [125]$$

For the sufficiently large value of  $M$  ( $M \geq 40$ , in our case), the results do not depend practically on the value of  $M$ . Because 95% of all experimental measurements usually lie in the interval  $(X_{av} - 2\sigma, X_{av} +$

$2\sigma$ ), we posit that excellent agreement is observed between the experimental and simulation results.

It is important to emphasize that **Figures 11 and 14** were obtained by using absolutely different approaches. While **Figure 11** was obtained as a result of extrapolating data from short term experiments, without any assumption of kinetic parameters, **Figure 14** was obtained assuming that we have the complete set of required parameters without directly using data of short term experiments.

As noted previously, the main advantage of deterministic models over the statistics-based models lies in the fact that deterministic models allow us to make predictions for environmental conditions that lie beyond the available experimental (calibration) data, because the predictions are analytic and based upon a sound physical model and because the prediction is constrained by the natural laws to that which is physically real. As an example, **Figure 15** shows the influence of electrolyte conductivity on the mean depth of the deepest pits from multiple, identical sample areas on the surface as a function of time. It is seen that the mean of the deepest pits on multiple, but equal, areas on the alloy surface is a very sensitive function of the external environment conductivity; this probably reflects primarily an enhanced throwing power of the coupling current from the pit mouth to the external surface where it is consumed by oxygen reduction. Thus, increasing the conductivity of the external environment allows the coupling current to be thrown a greater distance from the mouth because of the lower IR potential drop in the solution, with the result that the pit can access a larger area for oxygen reduction. Because the pit growth rate is related to the magnitude of the coupling current through Faraday's law, the pit depth is also predicted to increase. It is also important to note that, in all cases, the mean of the deepest pits on the surface is predicted to become constant after  $\sim 100$  days of exposure, simply reflecting that, at longer times, all the pits on the surface are 'dead' (repassivated). The critical question then is whether the deepest dead pits are sufficiently deep to nucleate cracks under the prevailing loading conditions.

The version of the Monte Carlo model that is described above deals only with the propagation of pitting corrosion damage. The example of Monte Carlo simulation that considers the transition of a pit into a crack can be found, for example, in Turnbull *et al.*<sup>118</sup> This model is based on mechanistic equations for pit and crack propagation rates (see eqns [70] and

[90]), with statistically distributed input parameters, and no models were assumed for the pit or crack growth processes. These unknown parameters are fitted to the available experimental data, and accordingly, it will be impossible to use this model for predicting corrosion damage under different environmental conditions.

It is important to note that, in the models that consider deterministically the propagation of ensemble of cracks, it would be necessary, in the general case, to take into account the possible mechanical interactions between multiple cracks.<sup>127</sup>

### 2.39.10 Examples of Deterministic Prediction of Corrosion Damage in Complicated Industrial Systems

In this section, we present two examples of the deterministic prediction of corrosion damage in complex industrial systems. The two systems chosen are both from the electric power industry, where corrosion has proven to be an important factor in determining the availability of the power generating facilities. Indeed, it has long been recognized that the management of

**Figure 16** Schematic of the primary coolant circuit of a BWR having external coolant pumps. The regions are identified as (1) core channels; (2) core bypass; (3) upper plenum; (4) mixing plenum; (5) upper downcomer; (6) lower downcomer; (7) recirculation system; (8) jet pump; (9) bottom of lower plenum; (10) top of lower plenum. **Figure 17** Calculated ECP (versus SHE) for the primary coolant circuit in the Leibstadt BWR operating under 'normal water chemistry' conditions (no hydrogen added to the feedwater). Reproduced from Macdonald, D. D.; Urquidí-Macdonald, M. *Corrosion* **1992**, *48*, 354–366.

the accumulation of corrosion damage, such that maintenance can be performed during scheduled outages, is an effective strategy for enhancing availability and for life extension. The primary purpose, here, however, is to convince the reader that the deterministic prediction of damage is practical and that such models may form the basis for the effective management of damage.

### 2.39.10.1 Cracking in Nuclear Reactors

The first example of the application of deterministic modeling of damage localized corrosion that we have chosen to describe in our work on modeling the accumulation of damage due to intergranular stress corrosion cracking (IGSCC) in sensitized Type 304 SS in the primary (liquid water) coolant circuit of a BWR.<sup>23</sup> This case is important because it illustrates the integration of the damage over the CEP taken by the reactor during normal operation. The reader will recall that the CEP is the path taken by the system in terms of those independent variables that have a significant impact on the rate of accumulation of damage as the system changes from the present state to the future state.

A schematic of the primary coolant circuit of a BWR with external coolant pumps is shown in [Figure 16](#), and the various components and regions in the flow circuit are identified in the caption.<sup>128</sup>

Plotted in [Figure 17](#) is the ECP calculated using the MPM (see [Section 2.39.4](#)) by first calibrating the radiolysis model (not the MPM) on Dresden II (a completely different reactor in Illinois) field data for the oxygen content of the coolant during operation and on another reactor (Duane–Arnold); these two reactors define the extremes of the US fleet of BWRs in their response to hydrogen added to the reactor feedwater.<sup>20,31,99</sup> These calculations predict that the ECP varies by about 250 mV around the entire coolant circuit when no hydrogen is added to the feedwater.

On the other hand, if significant hydrogen is added to the feedwater (e.g., 0.5 ppm), the corrosion potential is predicted to vary by about 0.9 V around the circuit. The Nuclear Regulatory Commission (NRC) has proposed a critical potential for intergranular stress corrosion cracking (IGSCC) in sensitized Type 304 SS of  $-0.23 \text{ V}_{\text{SHE}}$ ; if the corrosion potential lies below this value, no cracking will occur but for more positive values, cracks will nucleate and grow, and the utility cannot take credit for a 'no cracking environment.' In the case of 'normal water chemistry (NWC)' ([Figure 17](#), zero feedwater hydrogen), all components in the primary (liquid water) coolant circuit are predicted to be susceptible to IGSCC. Under 'hydrogen water chemistry (HWC)' ([Figure 18](#),  $[\text{H}_2]_{\text{FW}} = 0.50 \text{ ppm}$ ), significant regions of the coolant circuit are protected by the added hydrogen, including much of the recirculation piping system

and the Lower Downcomer, while other regions are not. This example demonstrates how modern modeling techniques (i.e., reaction kinetic analysis, RKA) can be used to specify the conditions that must be achieved in a complex chemical system in order to protect components against corrosion.

As indicated above, the CEP describes the path taken by the system in terms of the independent variables that have a significant impact on the process, resulting in corrosion damage as the system changes from the present state to the future state. Once this path is defined, the corrosion rate is integrated along the path to yield the integral damage. This concept is illustrated below with reference to intergranular stress corrosion cracking in the core shroud of a boiling water nuclear reactor. (The shroud is a stainless steel drum that surrounds the core containing the fuel rods. The shroud contains a circumferential weld (the 'H-3 weld') at the top, and the steel adjacent to the weld, in the so-called heat-affected zone, HAZ, is sensitized and hence is susceptible to IGSCC. The phenomenon of IGSCC has been responsible for billions of dollars of losses in the nuclear power industry during a period extending over 30 years.) For IGSCC in sensitized Type 304 SS, the important independent variables in determining the crack growth rate are stress, degree of sensitization (DOS), crack length, temperature, conductivity of the water, oxygen, hydrogen, and hydrogen

peroxide concentrations (all produced by the radiolysis of water or added, as in the case of  $H_2$ , for a reactor operating on hydrogen water chemistry), and water flow velocity. In turn, the concentrations of the redox species ( $H_2$ ,  $O_2$ , and  $H_2O_2$ ) determine the electrochemical corrosion potential (ECP), upon which the crack growth rate is exponentially dependent. Accordingly, the independent variables defining the CEP for the crack in the shroud ID surface within the HAZ of the weld are temperature, degree of sensitization (DOS) of the steel, crack length, tensile stress (residual and operational), water conductivity, ECP, and flow velocity. Thus, the CEP is defined in terms of the variations in each of these quantities as the reactor changes during the ten years of operation.

Figure 19 shows the operating history of the reactor in terms of reactor power (which defines the temperature and the bulk coolant flow rate) and hydrogen added to the feedwater ( $H_2$  has a large impact on the ECP – see Figures 17 and 18). This generic reactor was operating on HWC, with hydrogen being added only when the reactor is operating, not during shutdown, and the damage, in terms of the crack length, was calculated by integrating the crack growth rate over the CEP for a period of 10 years.

The predicted damage is summarized in Figure 20, in which are plotted crack length (in centimeters) versus time curves for three operating protocols:

**Figure 18** Calculated ECP (vs. SHE) for the primary coolant circuit in the Leibstadt BWR operating under 'hydrogen water chemistry' conditions (0.50 ppm hydrogen added to the feedwater). Reproduced from Macdonald, D. D.; Balachov, I.; Engelhardt, G. R. *Power Plant Chem.* **1999**, 1, 9–16.

**Figure 19** Corrosion evolutionary path (CEP) defined in terms of the prime variables of reactor power and hydrogen added to the reactor feedwater. Reproduced from Macdonald, D. D.; Balachov, I.; Engelhardt, G. R. *Power Plant Chem.* **1999**, 1, 9–16.

**Figure 20** Integrated damage functions (crack length) versus reactor operating time for three operating scenarios: (1) normal water chemistry, (2) hydrogen water chemistry (1 ppm H<sub>2</sub> in the reactor feedwater), (3) NWC for 5 years followed by HWC for the remaining 5 years. Reproduced from Macdonald, D. D.; Balachov, I.; Engelhardt, G. R. *Power Plant Chem.* **1999**, 1, 9–16.

(1) normal water chemistry (NWC), where no hydrogen is added to the reactor coolant (diamonds), (2) hydrogen water chemistry (1 ppm H<sub>2</sub> in the reactor feedwater over the entire 10-year operating period, squares), and (3) NWC for 5 years followed by HWC for the remaining 5 years (triangles). The various ‘jigs

and jogs’ in the data are not artifacts caused by imprecise calculation, but represent changes in crack growth rate with the changing conditions along the CEP, particularly when the reactor is shut down and started up. During entering and exiting a shutdown period, some of which occur for refueling of the reactor, the hydrogen concentration, coolant conductivity, temperature, coolant flow velocity, and stress (although the stress on the crack was assumed to be primarily residual and hence, is assumed to be constant in the simulations described above) change markedly, but the impact on the overall damage is only small, because the shutdown and start up periods are short. It is seen from **Figure 20** that the crack growth rate (gradient of the curve) decreases with time. This is the consequence of coupling between the internal and external environments of the crack, as postulated in the coupled environment fracture model (CEFM) (see Macdonald *et al.*<sup>23</sup> and citations therein and the corresponding section of this article). Thus, as the crack grows in length under constant potential conditions, a larger IR potential drop occurs down the crack, resulting in a lower potential drop being available on the external surface for the reduction of oxygen or the evolution of hydrogen, thereby resulting in a reduction of the coupling current and hence, a lower crack growth rate. (Note that the crack cannot grow faster than the coupling current can be consumed on the external surface by oxygen reduction and/or hydrogen evolution, and it has been established experimentally

that the crack growth rate is linearly related to the coupling current.)

Under NWC, the crack is predicted to grow by about 2.2 cm over the 10 years of operation (note that we assume an initial crack length of 0.5 cm). If HWC (where 1 ppm of  $H_2$  is added to the reactor coolant water only during operation, see Figure 19), the crack is estimated to grow by only 0.6 cm over the 10-year operating period, a substantial reduction in the damage. If, on the other hand, the reactor operated for the first 5 years on NWC (no added hydrogen) and then switched to HWC, the damage (increase in crack length) is predicted to be 1.7 cm. The progression of damage is clearly governed by the 'law of decreasing returns,' in that the damage avoided in the last 5 years by implementing HWC (0.5 cm) is substantially less than that incurred under NWC in the first 5 years (1.6 cm). This is entirely due to the dependence of the crack growth rate on crack length, a dependence that was never previously recognized in crack growth-rate studies. Clearly, predictions of this type are of considerable value, because they allow the benefits to be defined in a cost/benefit analysis. The cost of installing HWC in a BWR is significant because of the need to store considerable amounts of hydrogen on site and because of the need to shield personnel against the production of radioactive  $^{16}NH_3$  that forms by neutron bombardment of oxygen in water ( $^1n_0 + ^{16}O_8 \rightarrow ^{16}N_7 + ^1p_1$ ) under the reducing conditions that exist in the coolant circuit under HWC operating

conditions. Note that  $^{16}N_7$  is a strong  $\gamma$ -photon emitter.

At this point, it is worthwhile to enquire how accurate the prediction might be for a system that is as complex as an operating BWR. Data published by Tang *et al.*<sup>129</sup> (see also Macdonald *et al.*<sup>23</sup>) for a crack adjacent to the H-3 weld in a reactor operating in Taiwan affords an opportunity to assess the accuracy, as depicted in Figure 21. The depth of the crack was assessed by inspection at times of 10 and 20 months after Outage 11 and the ALERT code was fit to the datum for the shorter time, essentially by adjusting the time of nucleation of the crack, such that the calculated and measured crack depth coincided. ALERT was then used to calculate the crack depth at the longer, 20-month time after Outage 11, and the comparison with the measured value is displayed in the figure. Excellent agreement is obtained, with the small residual difference being attributed to uncertainty in the operating history of the reactor.

This example has been presented because it illustrates the application of damage function analysis (DFA) to the deterministic prediction of damage in a complex industrial system. It also illustrates the role of, and the need for, careful characterization of the CEP. It is the opinion of the authors that a water-cooled nuclear reactor is comparable in complexity to, say, an oil production system, and that meaningful damage prediction calculations are possible on the basis of DFA (or any other deterministic protocol), provided that the CEP is carefully defined.

**Figure 21** Depth of a crack at the H3 weld in the shroud as a function of time after Outage 11. (♦) Values calculated by ALERT.<sup>19,23</sup> Experimental data reported by Tang *et al.*<sup>129</sup>

Of course, the reward for being able to make such calculations is that it then becomes possible to answer the all-important ‘what if’ questions, such as: ‘What damage will I incur if I operate in this manner?’ or ‘If I take this corrective measure, can I operate with reasonable certainty to the next outage?’ Answers to questions of this type can have significant economic implications.

### 2.39.10.2 Low Pressure Steam Turbines

Another complex industrial system that has been modeled deterministically with regard to the accumulation of localized corrosion damage is low pressure steam turbines (LPSTs). Failure of LPSTs generally occurs via the cracking of the rotor, disk, or blades, from cracks that nucleate at pits.

Below we will show some results of calculating the probability of failure,  $P_f$ , of LPSTs by using the deterministic Monte Carlo simulation method that has been described above.<sup>130</sup> By definition,  $P_f$  is the probability that at least one corrosion event in any form (pit, stress corrosion crack, or fatigue crack) reaches a depth,  $a_{cr}$ , at a given observation time,  $t$ , where  $a_{cr}$  in this case, is the critical dimension (e.g., the stress corrosion crack length at which unstable, rapid mechanical fracture and sudden failure occurs). Using the Monte Carlo simulation method, we can calculate  $P_f$  in a straightforward way. Let us assume that we make  $M$  calculations of the depth of the deepest corrosion event,  $x^*$ , and, in  $M_f$  cases ( $M_f \leq M$ ),  $x^* > a_{cr}$  for a given observation time,  $t$ . In this case,  $P_f(a_{cr}, t)$  is defined as

$$P_f = \frac{M_f}{M} \quad [126]$$

for sufficiently large  $M$ .

In particular, it was found that the failure probability is a very sensitive function of the conditions that exist in a low pressure steam turbine (LPST)

**Table 3** Assumed operational cycle parameters for the development of corrosion fatigue in low pressure steam turbine blades

Shutdown	Operation cycle
$t = 100$ h	$t = 500$ h
$\sigma = 0$	$\sigma = \sigma_m + 0.5 \Delta \sigma \sin(2\pi ft)$
	$\sigma_m = 84$ ksi, $\Delta \sigma = 4$ ksi, $f = 60$ Hz
$T = 25^\circ\text{C}$	$T = 95^\circ\text{C}$

**Figure 23** Calculated failure probability for LP steam turbine discs as a function of oxygen concentration for different chloride concentrations in the electrolyte film during the shutdown period. Other parameters are the same as in Table 4.

during shutdown, including the oxygen concentration, chloride concentration, and the fraction of the time spent under shutdown versus operation, if the shutdown environment is not deaerated, and the steel

**Figure 24** Probability of failure of a turbine disk as a function of temperature during the shutdown period. The oxygen concentration during shutdown period is 4.5 ppm. Other parameters are the same as in Table 4.

**Figure 25** Probability of failure of a turbine disk as a function of pH during the shutdown period. The oxygen concentration during shutdown period is 5.2 ppm. Other parameters are the same as in Table 4.

**Figure 26** Calculated failure probability for LP steam turbine blades versus the fraction of the time spent in shutdown.

**Figure 27** Calculated failure probability for LP steam turbine discs versus the fraction of the time spent in shutdown.

surfaces are not washed free of chloride ion. It is important to note that the calculations were made by using experimentally determined electrochemical parameters for Type 403 SS in the case of determining failure in blades (where CF takes place) and A470/471 steels in the case of determining failure in discs and rotors (where SCC takes place).<sup>131</sup>

For illustrative purposes, we present below only some examples of the influence of environmental parameters on the probability of failure of blades and discs in low pressure steam turbines. The assumed operating cycle parameters for the case of stress corrosion cracking can be found in Tables 3 and 4. This information defines the CEP.

The failure probabilities plotted in Figures 22–27 as a function of  $[O_2]$ ,  $[Cl^-]$ , temperature, pH, and fraction of the time spent in shutdown under aerated conditions all during the shutdown period, were calculated for 219 shutdown–operation cycles over 15 years, assuming instantaneous nucleation (all pits nucleating during the first shut down) and that all cycles are identical. This particular CEP was chosen for modeling convenience; more complicated CEPs, in which the cycle time and other parameters are varied over realistic ranges, are easily enacted. The critical crack length was assumed to be 0.5 cm, and crack growth was determined to occur primarily by mechanical fatigue during operation.

The calculated failure probabilities plotted in Figures 22 and 23 are clearly sensitive functions of both the oxygen concentration and the chloride concentration in the condensate on the blade or disk surface left over from operation. Increasing the oxygen concentration under open shutdown (i.e., opening the turbine to the atmosphere) displaces the corrosion potential in the positive direction and hence

increases the pit nucleation and propagation rates, thereby resulting in enhanced pitting damage. Upon subsequent startup, the pits act as stress-raisers for the nucleation of cracks (SCC and corrosion fatigue) and hence lead to an increase in the failure probability. The important lesson to be learned from this plot, and from many simulations of this type, is that deaeration of the turbine upon shutdown should be an effective method of protecting low pressure steam turbines against blade and disc failure after subsequent start-up.

**Figures 22 and 23** also show that the failure probability,  $P_f$ , decreases sharply to a very low value (essentially zero) as  $[\text{Cl}^-]$  is lowered below 35 ppm. This provides a second strategy for reducing, or even eliminating the failure of discs and blades, reducing the chloride concentration of  $\text{Cl}^-$  on the surfaces immediately upon shutdown. This would be most easily instituted by washing the blade and disc surfaces with pure (chloride-free) water immediately upon shutdown of the turbine. In fact, an even more effective strategy would be to combine turbine surface washing with nitrogen blanketing. Given that turbine failure costs anywhere between \$10 million and \$100 million per event, depending upon the nature of the failure, an incentive certainly exists for the utilities to explore the strategies identified above.

The temperature of shutdown is also predicted, in certain situations, to have a visible effect on the failure probability (see **Figure 24**), primarily through the pit growth rate. While this is a substantial reduction, the investment in the necessary facilities to cool a turbine after shutdown is possibly too great to be cost effective, but the desired effect might be achieved through conventional air conditioning.

The remaining environmental variable that is amenable to change is the pH. This variable may be changed by doping the boiler water of the steam with pH buffers, including ammonia, various amines, and systems such as boric acid–hydroxide systems. However, our predictions are that pH has relatively little impact on the failure probability (see **Figure 25**). Thus, the gain that might be achieved in turbine service life possibly would not warrant instituting a major chemistry change upon the basis of enhancing turbine blade and disc life alone.

**Figures 26 and 27** clearly show that the probability of failure increases rapidly with the time spent under aerated conditions during shutdown. That is why the reduction of this time could be an effective method of protecting low pressure steam turbines against blade and disc failure.

It must be emphasized that prediction of the probability of failure in LPTS can also be done on the basis of damage function analysis. Examples of the corresponding calculations can be found in Engelhardt *et al.*<sup>132</sup> and Engelhardt and Macdonald.<sup>131</sup>

## 2.39.11 Conclusions

The purpose of this chapter is to introduce the reader to deterministic methods that have been developed to predict the accumulation of corrosion damage in complex industrial systems. That such predictions can be made is now well beyond question, and it is expected that determinism will rapidly develop as the philosophy of choice in making damage predictions. Because practicing scientists and engineers have seldom taken a course on the philosophies of prediction, few have been exposed to the modeling choices that are available, ranging from empiricism, to ‘mechanistic models,’ to models that are characterized by varying degrees of determinism. This latter caveat recognizes that, in practice, ‘determinism’ is an ideal concept that is seldom, if ever, achieved in modeling in pure form. From a practical viewpoint, however, determinism offers a methodology that means minimal calibration, because the dependent/independent variable relationships are captured within the constitutive equations of the model, rather than by calibration, as is the case for an empirical model. As noted above, failure in industrial systems is, by and large, a very rare event, so that almost no chance exists for establishing reliable dependent–independent variable relationships by direct calibration.

Another great advantage of deterministic models is that they draw upon the wealth of scientific experience by constraining the solutions of the constitutive equations to that which is ‘physically real’ via the natural laws. This feature cannot be overemphasized, as it greatly reduces the need for calibration, provides a condition that must be satisfied and does not arise from the model itself (the model is described by the constitutive equations). If the constraints are absent, or are not imposed, the model may still be ‘mechanistic,’ but it clearly lacks the predictive power offered by determinism.

In making predictions with any model, be it empirical or deterministic, it is essential to define the CEP, which is the path taken by the system in terms of those independent variables that have a significant impact on the damage accumulation rate as the system changes from the present state

to the future state. Because, the future cannot generally be predicted with certainty, the CEP is most often synthesized to present 'what if' scenarios of operation. These scenarios coupled with economic analyses, may be used to identify the most cost-effective modes of operation and hence, are a valuable financial planning tool. Similarly, the CEP may be designed to ascertain the probability that failure will not have occurred by the time of the next scheduled inspection, which, given the deleterious cost of unscheduled outages, again becomes a valuable financial planning tool. Finally, it is evident that the tools discussed in this chapter are capable of providing valuable input to the design of complex industrial systems, particularly in the light of the fact that corrosion issues are seldom, if ever, given more than cursory examination.

One of the significant advantages of integrating the damage along the CEP to yield the damage function (DF) is that the process may be applied to historical data from which the CEP may be defined with considerable accuracy. In this mode, the predicted damage function becomes a means of accessing the veracity of the model and the damage prediction process. In fact, this type of calculation should always be performed, if for no other reason than that it affords a means of customizing the algorithm to the system of interest. Customization may require the adjustment of values for poorly known parameters in the model or may even require modification of the code itself. In any event, the code becomes the 'alter ego' of the system and provides a means of accurately predicting the accumulation of damage under conditions where the CEP can be defined with historical accuracy.

## Glossary

**Akaganeite** Hydrated iron oxide,  $\beta$ -FeO(OH,Cl), that is stable in the presence of chloride ions and thus generally forms in seawater.

**Goethite** Stable form of hydrated iron oxide, FeOOH and thus commonly found in nature.

**LAMM phase** The structure of the passive film on iron.

**Lepidocrocite** Metastable form of hydrated iron oxide, FeOOH and commonly found during atmospheric corrosion of iron-based alloys.

## Abbreviations

**ALWC** Accelerated low water corrosion

**BISRA** British Iron and Steel Research Association

**BS EN** British Standard European Norm

**FAC** Flow-assisted corrosion  
**ISO** International Standards Organisation  
**MIC** Microbiologically assisted corrosion  
**NACE** National Association of Corrosion Engineers  
**NBS** National Bureau of Standards  
**RH** Relative humidity  
**SIMS** Secondary ion mass spectrometry

## Symbols

**ads** Adsorbed  
**C** Concentration of species  
**F** The Faraday or Faraday's constant  
 **$i_{lim}$**  Diffusion limited current density  
 **$k$**  Mass transfer coefficient  
 **$n$**  Number of electrons transferred in an electrochemical reaction  
 **$t$**  Time  
 **$\alpha$**  Ferrite  
 **$\gamma$**  Austenite  
 **$\omega$**  Angular velocity

## 3.01.1 Introduction

### 3.01.1.1 Historical Perspective

Prior to the sustained and deliberate production of iron, there is some evidence that ferrous materials (i.e., iron–nickel) derived from meteors were used intermittently in antiquity although they must have been relatively rare. The development of iron production dates back more than 3000 years (1500–1200 BC) when ferrous ores began to be smelted in the ancient Near East civilizations (i.e., Iran, India, Mesopotamia, and Anatolia), which apparently coincided with a shortage of tin for the production of bronze. In Europe, iron began to be produced somewhat later, in the period from the eighth to the sixth century BC.<sup>1</sup>

A feature of early iron production was the relatively limited temperature that the furnaces of the time could achieve. In practice, this was not necessarily a disadvantage as the process involved the use of wood charcoal to reduce iron ore in the solid state leaving a porous mass of relatively pure solid iron (of variable composition) mixed with the ore residues (slag) resulting in a 'bloom.' Subsequently, the skill of the smith was required to repeatedly forge the hot bloom in order to remove the majority of the slag inclusions, resulting in a product known as 'wrought' (i.e., forged) iron. Subsequent adjustments in carbon

content were made by cementation type processes, effectively by successively placing the semifinished object in hot charcoal or air.

This method of iron production remained, essentially unchanged in Europe, for 1500 years. However, in China development of iron smelting techniques that were able to reach temperatures of  $\sim 1150^{\circ}\text{C}$  and, consequently, were able to melt cast iron (when combined with  $\sim 4\%$  carbon) was achieved in  $\sim 500$  BC. Methods for reducing the carbon content of such cast irons were necessary in order to achieve a malleable material, and this was achieved by heating the molten material in air with stirring. During this process iron oxide, formed by oxidation of the molten metal, was stirred into the melt and reacted with dissolved carbon producing carbon monoxide, thus lowering the overall carbon content. In Europe, the development of water power was applied to the bloomery forging process in order to increase production of steels from 1000 AD onwards. However, cast irons were not generally produced as knowledge of how to reliably reduce their carbon content was not introduced until the Middle Ages (i.e., from 1100 to 1300 AD onwards) where a process similar to the Chinese one was used in so-called 'puddling' furnaces. Later developments included the manufacture of limited quantities of high quality steels via crucible and similar methods.

Large scale cast iron manufacture in blast furnaces developed only after the switch from wood charcoal (a limited resource) to coke derived from coal in the late seventeenth and early eighteenth centuries, while mass production of steel had to wait until Bessemer's invention of the converter in 1855, which utilized a hot air draught from below to remove carbon by reaction with oxygen. Until these developments, steel was an expensive commodity used only for niche applications where its combination of properties was essential. The widespread production of steel lowered its cost such that it could be used for an increasing number of applications, and eventually mild steel completely replaced wrought iron. Advances in the production of steel to further lower costs have continued as have alloy developments to further expand the use of ferrous materials. Nowadays, steel is a ubiquitous and essential component of modern life.

### 3.01.1.2 Iron–carbon Alloys

#### 3.01.1.2.1 Phase diagram

Carbon is generally present in steel at room temperature as iron carbide ( $\text{Fe}_3\text{C}$  or cementite). This phase

is strictly metastable to decomposition to graphite and iron, however, the reaction is very sluggish at lower carbon contents although graphite evidently forms preferentially in, for example, grey cast irons. The iron–carbon phase diagram (drawn with cementite as the stable phase) is reproduced in **Figure 1**. The room temperature allotrope of unalloyed iron is known as ferrite ( $\alpha$ -iron) and has a body-centered cubic structure; above 910 °C, this transforms to  $\gamma$ -iron or austenite (face-centered cubic) that, in turn, transforms to  $\delta$ -iron (also body-centered cubic) above 1394 °C prior to melting at 1538 °C. Alloying with carbon lowers the melting point, eventually to the Fe–C eutectic temperature of 1140 °C forming effectively cast iron. Note that the solubility of carbon in ferrite is extremely low (around 0.03% at 723 °C and <0.01% at room temperature).

For practical purposes, iron may be defined as a material that contains carbon only up to its solubility limit in ferrite (i.e., <0.03% C by mass), while steel contains carbon within its solubility limits in austenite (i.e., from ~0.03% to 2.05% C by mass). In practice, most steels contain typically from 0.05% to 1.0% of carbon, with the majority of alloys lying at the lower end of this scale (i.e., 0.05–0.5% carbon),

although some specialized alloys may have compositions that lie outside these values. Steel also contains elements such as silicon, phosphorus, and sulfur that arise inevitably from the steel-making process and which may affect properties detrimentally unless limited or controlled. For example, sulfur forms a low melting point eutectic with iron, and hence, limits the ability of the steel to be processed at higher temperatures. Thus, plain carbon steels traditionally contain sufficient added manganese (15–20 times that of sulfur) to ‘mop-up’ the sulfur via the formation of MnS precipitates. However, increased amounts of manganese are also beneficial in, for example, solid solution hardening of ferrite, and improving the ductility and toughness of the alloy.

‘Plain carbon steel’ may be defined as an alloy of iron with carbon where the total quantity of alloying elements is less than 2% by mass with compositional limits of 0.6% for copper, 1.65% for manganese, 0.04% for phosphorus, 0.6% for silicon, and 0.05% for sulfur and where no other elements are deliberately added in order to provide a specific property or attribute. This somewhat convoluted definition is necessary to exclude some low-alloyed steels (e.g., with small amounts of chromium, cobalt, niobium, molybdenum, nickel,

**Figure 1** Iron–carbon phase diagram (note ‘perlite’ is an alternative spelling of ‘pearlite’). Reproduced here under the Gnu Free Documentation License from its original source at [www.wikipedia.org](http://www.wikipedia.org).

titanium, vanadium, etc.) that otherwise might be classed as 'plain carbon.' In contrast, 'low alloy steels' contain deliberate additions of alloying elements up to 10% by weight so as to develop enhanced mechanical properties. Finally, 'high alloy steels' contain more than 10% by weight of alloying additions and include materials such as stainless, tool, and maraging steels. Alloying additions may also be classed with respect to their effects on the stability of the ferrite and austenite phase regions. Thus, carbon, nitrogen, manganese, nickel, and cobalt all tend to expand the austenite phase region (i.e., are austenite stabilizers), while silicon, chromium, molybdenum, niobium, vanadium are ferrite stabilizers.

Carbon steels typically comprise more than 85% of steels produced and shipped worldwide and are, therefore, by far the most frequently used iron-carbon alloy. It is usual to categorize steels by their carbon content, but the specific boundaries are not well-defined. Generally, low-carbon steel ('dead mild' steel) contains up to ~0.15% carbon and 0.3–0.6% manganese by mass. It has relatively low strength but high formability, and is used typically in sheet and strip products. Mild steel contains from 0.15% to 0.3% carbon and is used in flat rolled products where higher strengths are required. For structural steelwork, plates and rolled sections, forgings and stampings of the manganese content can be increased to ~1.5% to improve toughness. Medium-carbon steels with 0.3–0.6% carbon and 0.60–1.65% manganese allow the use of quenched and tempered heat treatments with applications in axles, gears, forgings, rails, etc. Finally high-carbon steels containing 0.6–1.0% carbon and 0.3–0.6% manganese are used for high strength applications such as springs and wires. Materials with carbon content greater than 1% are typically insufficiently tough to be used for structural purposes, but find application where high hardness and abrasion resistance is required, for example, as machine tools, saw blades, etc.

### 3.01.1.2.2 Equilibrium microstructures

The iron-carbon phase diagram can be seen to be dominated by the pearlite eutectoid reaction (important for steel) and the ledeburite eutectic reaction (important for cast iron, and not considered further here). The pearlite reaction comprises the diffusion-controlled decomposition of austenite to ferrite and iron carbide at the eutectoid composition (~0.8% C by mass) and temperature (723 °C):

At carbon content below the eutectoid composition (hypoeutectoid <0.8% C), ferrite will form first, while at higher carbon content cementite will form first (hypereutectoid >0.8% C); both phases nucleating preferentially at the austenite grain boundaries. Pearlite (or perlite) is not a phase itself but it is rather a two-phase mixture of ferrite (~88%) and cementite (~12%) that forms in alternating laths (strips); it is so-called because of its characteristic pearl-like appearance. **Figure 2** shows representative steel microstructures of varying compositions. The individual laths of ferrite and cementite are often not easily resolved in commercial alloys using optical microscopy, however, they are visible in the higher carbon content material, **Figure 2(c)**.

Since the transformation is diffusion controlled, the spacing between the ferrite and cementite laths in pearlite varies as a function of cooling rate with slow (i.e., furnace) cooling giving the widest spacing and faster cooling giving closer spacing. Ferrite itself has a rather low yield stress, so the overall strength of the steel is dependent on the nature and spacing of second phase particles, including the individual pearlite colonies as well as the pearlite lamellae and any other phase that happens to be present.

### 3.01.1.2.3 Nonequilibrium microstructures

If steel is cooled faster than the rate at which carbon can be rejected by diffusion from the austenite lattice, the consequent formation of equilibrium iron carbide is partially or wholly suppressed. Under these circumstances, the austenite cannot retain the excess of carbon within its structure due to its thermodynamic instability and must transform via an alternative mechanism. At sufficiently low temperatures where essentially no significant diffusion of carbon can occur, the thermodynamic driving force is able to overcome the lattice strains inherent in a diffusionless (shear) transformation and martensite, which is a distorted body-centered tetragonal structure, will form directly. At intermediate temperatures where limited diffusion of carbon can still occur, the bainite structure forms by transformation of austenite to carbon-supersaturated ferrite with the subsequent diffusion of carbon and the precipitation of carbides either in untransformed austenite (upper bainite) or within the ferrite (lower bainite). The detailed mechanisms of these transformations and their microstructures are complex and beyond the scope of this work, however, the concept is important in understanding the properties of steel and particularly how they may be altered beneficially by heat treatment.

The advantage in rapid cooling (or quenching) of steel is that carbon is then held uniformly in the martensite phase in supersaturated solid solution. Martensite itself is very brittle and hard and, consequently, has limited uses. However, when martensite is reheated sufficiently, the retained carbon is able to diffuse and precipitate as fine carbides that are relatively evenly distributed in the material. In contrast, in pearlitic steel, the strengthening phase is both unevenly distributed (i.e., in pearlite

colonies) and present in thin strips that are more likely to act as crack initiators. **Figure 3(a)** shows a quenched martensitic structure, while **Figure 3(b)** shows the same material but after aging (tempering) at an elevated temperature in order to precipitate the carbide particles. The even distribution of carbides is evident and compared with a pearlitic microstructure of similar carbon content, results in greatly increased fracture toughness at similar yield stress.

**Figure 2** Pearlitic microstructures in steel (air cooled) (a) Hypoeutectoid (0.2% C; ferrite, light, with pearlite colonies, dark, elsewhere in the structure). (b) Eutectoid composition (0.8% C; fully pearlitic). (c) Hypereutectoid (1.3% C; cementite has nucleated on former austenite grain boundaries with pearlite elsewhere in the structure). **Figure 3** Annealed, compared with quenched and tempered, steel microstructures. (a) 0.31% C annealed showing pearlite colonies of ferrite and cementite between grains of ferrite. (b) as (a) but quenched to form martensite then tempered to precipitate a fine carbide distribution of cementite. Reproduced by kind permission of Cochrane, R. F. University of Leeds and the DoITPoMS Micrograph Library ([www.doitpoms.ac.uk](http://www.doitpoms.ac.uk)).

### 3.01.1.3 Mechanical and Physical Properties

Alloying greatly decreases the thermal and electrical conductivities of pure iron but has little effect on other physical properties such as the elastic modulus. Regarding mechanical properties, pure iron (ferrite) is soft and malleable but work-hardens rapidly, **Table 1**. Ferrite can be solid-solution strengthened by either interstitial (e.g., C, N, and P) or substitutional (e.g., Si and Mn) alloying additions. Silicon and manganese, which are always present in iron at levels of  $\sim 0.3$ – $0.5\%$ , provide some solid-solution strengthening of the ferrite; phosphorus gives much stronger solid-solution strengthening but is not commonly added deliberately as it can greatly reduce toughness. Carbon and nitrogen have the greatest potential effect but have very low solubilities in ferrite.

As noted above, carbon-containing alloys (i.e., steels) are mainly strengthened by the formation of second phase carbide precipitates. In plain carbon steels, these comprise iron carbides that may form as pearlite colonies or, after quenching and tempering, as a fine carbide distribution in the microstructure. In low alloy steels, the addition of elements such as molybdenum, titanium, vanadium, chromium, niobium, and nickel either promote the formation of alloy carbides or control the formation of martensite and/or the favorable precipitation of iron carbides.

Like other body-centered cubic metals, steels are subject to a ductile-to-brittle transition and this may occur close to ambient temperatures depending upon the type of steel, its alloying contents (including carbon, manganese, etc.), and how it has been processed. Clearly, it is usually advisable for the ductile-to-brittle transition temperature to fall well below operating temperatures in order to ensure adequate fracture toughness during service. Key factors that influence the transition temperature include microstructure, carbide distribution, internal stress, and the composition of the ferrite phase.

It is beyond the scope of this chapter to discuss the detailed effect of microstructure, composition, etc. on the overall mechanical properties of steels and, hence, interested readers are directed to Llewellyn *et al.*<sup>3</sup> and Bhadeshia *et al.*<sup>4</sup> for further information.

### 3.01.1.4 Processing

#### 3.01.1.4.1 Heat treatment

The main purpose of heat treatment is to optimize the mechanical properties of a particular steel grade. This typically involves a single or a series of heating and cooling operations designed to produce an optimum microstructure for the particular end use. These processes can be divided conveniently into: softening (or annealing), normalizing, hardening, and tempering treatments.

General process annealing is carried out on cold-worked materials in order to relieve internal stresses and/or to soften them prior to further cold work. Full annealing is carried out by heating the steel into the austenite phase region (if a hypoeutectoid steel), or just above the eutectoid temperature (if hypereutectoid) followed by slow (e.g., furnace) cooling that results in a relatively coarse lamellar pearlite. Normalizing involves the same heat treatment, however, the cooling is more rapid and carried out in air, which results in a decrease in the size of microstructural features (grain size and pearlite lamellae spacing) and consequent increased final hardness.

Hardening of hypoeutectoid steels involves heating into the austenite phase region followed by rapid cooling (or quenching). As the cooling rate is increased, the formation of pearlite occurs at lower temperatures resulting in an increasingly finer lamellar structure, until at a critical cooling rate that depends on the alloy content of the steel, martensite is formed directly. Tempering of hardened steel is achieved by reheating to various temperatures below the austenite boundary with the intention to relieve internal stresses

**Table 1** Generic properties for annealed ferrous alloys

Property	Iron (>99.9% Fe)	Carbon steel (0.15%C)	Stainless steel (18%Cr, 10%Ni)
Density ( $\text{Mg m}^{-3}$ )	7.86	7.86	8.00
Elastic modulus (GPa)	200	200	195
Thermal conductivity ( $\text{W m}^{-1} \text{K}^{-1}$ )	76.2	20–65	16.2
Electrical conductivity ( $10^6 \Omega^{-1} \text{m}^{-1}$ )	11.2	6.23	1.45
Ultimate tensile strength (MPa)	>200	385	565
Proof Stress at 0.2% strain (MPa)	$\sim 70$	285	210
Elongation (%)	>40	35	55

Source: Data taken from Smithells Metals Handbook.

induced by quenching and to permit the diffusion of carbon retained in the martensite matrix in order to precipitate a relatively even distribution of carbides. Tempering at 100–200 °C is sufficient to relieve quenching stresses only. However, at temperatures between 200 °C and 450 °C the martensite will decompose into ferrite by precipitation of fine particles of carbide throughout the structure decreasing yield strength but increasing toughness. At higher temperatures still (i.e., 450–650 °C) fewer but larger carbide particles are produced further increasing the toughness and reducing the strength. Microstructures formed in this way are known as tempered martensites and vary in microstructure from relatively large ferrite grains containing second phase carbides to small, fine-grained structures similar to bainite. Generically, these steels are known as quenched and tempered.

The details for steel heat treatments are complex and those given above merely summarize the main elements; further details can be found in *Steel Heat Treatment Handbook*.<sup>5</sup> In some cases, heat treatment alone cannot provide the desired structure, and some form of thermo-mechanical treatment is necessary. For example, some low alloy and microalloyed steels (high-strength low-alloy steels) develop exceptional combinations of strength, toughness, and low ductile-to-brittle transition temperature by virtue of a controlled process combining a gradually decreasing temperature with simultaneous rolling of the steel.

After processing (rolling, forging, forming, etc.) at elevated temperatures, a layer of oxide, called millscale, inevitably would have formed on the metal surface. The structure of millscale consists of three superimposed layers of iron oxides in progressively higher states of oxidation from the metal side outwards: ferrous oxide (FeO) on the inside, magnetite (Fe<sub>3</sub>O<sub>4</sub>) in the middle, and ferric oxide (Fe<sub>2</sub>O<sub>3</sub>) on the outside. The relative portions of the three oxides vary with the processing temperatures. A typical millscale on 9.5 mm mild steel plate would be ~50 µm thick, and contain ~70% FeO, 20% Fe<sub>3</sub>O<sub>4</sub>, and 10% Fe<sub>2</sub>O<sub>3</sub>. If millscale was perfectly adherent, continuous, and impermeable, it would form a good protective coating, but in practice millscale is liable to crack and flake off exposing the underlying metal. During atmospheric exposure, the presence of millscale on the steel may reduce the corrosion rate over comparatively short periods, but over longer periods, the rate tends to rise as the oxide flakes off the surface. In water, severe pitting of the steel may occur if large amounts of millscale are present on the surface.

For example, pits up to 1.25 mm deep were found on as-rolled steel specimens after 6 months immersion in sea-water at Gosport.<sup>6</sup> It follows that for most practical purposes where steel is exposed without a protective coating, or indeed to achieve effective coatings adhesion to the substrate, it is essential to remove all millscale either before putting components into service or prior to application of a protective coating.

#### **3.01.1.4.2 Mechanical deformation**

The vast majority of steel products are produced by mechanical deformation either while ‘hot’ (i.e., above the recrystallization temperature of the alloy) or ‘cold’ (i.e., below the recrystallization temperature); in the latter case, if continued processing is required, periodic annealing is necessary in order to remove the effects of work-hardening. Such processes include: rolling (plate, strip, and bar products, etc.), forging, stamping, wire drawing, etc. Both hot and cold deformation will produce a varying degree of banding and texture in the resultant microstructure, which may result in properties that vary according to the deformation direction, [Figure 4](#). Nonmetallic second-phase inclusions that originally derive typically from slag materials incorporated during the steel-making process will tend to form stringers in the metal during rolling operations. These can form planes of weakness in the steel, although modern clean steel making technology has greatly reduced the volume fraction and distribution of such unwanted second phases.

#### **3.01.1.4.3 Metallurgical influences on corrosion**

Generally, the process of manufacture has no appreciable effect on the corrosion characteristics of carbon steel. Slight variations in composition that inevitably occur from batch to batch in steels of the same quality have little effect with the exception of a limited number of elements in a small (but important) number of applications. For example, the addition of ~0.2% of copper results in a two- to threefold reduction in the atmospheric corrosion rate compared with a copper-free steel.<sup>7,8</sup> Variation in other alloying additions in carbon steel affects the corrosion rate to a marginal degree, the tendency being for the rate to decrease with increasing content of carbon, manganese, and silicon. Thus, steel containing 0.2% of silicon rusts in air ~10% slower than an otherwise similar steel containing 0.02% of silicon. Otherwise, all ordinary ferrous structural materials, that is, carbon and low-alloy steels, corrode at virtually the same rate when immersed in natural waters.

As shown in the historic data of **Table 2**, the process of manufacture and the composition of mild steel do not affect its corrosion rate appreciably.<sup>9</sup>

In carbon steels, the effect of microstructural anisotropy caused by processing is also generally not significant. Thus, in seawater immersion tests, carried out to determine the effects of rolling direction and tensile stress on the corrosion of a steel containing 0.14% C, 0.47% Mn and 0.04% Si,<sup>10</sup> specimens were cut from plates parallel to and perpendicular to the rolling direction. There was little difference in general corrosion performance, although pitting was somewhat worse on the plate cut parallel to rolling.

For low alloy steels generally under immersed conditions, alloying additions of at least 3% (e.g., of chromium, nickel, etc.) are necessary to obtain any marked improvement in the corrosion-resistance.

The main elements that alter the rate of corrosion of low alloy steels when immersed in natural waters are aluminum, copper, chromium, molybdenum, and nickel, but other additions, for example, manganese, silicon, phosphorus, and sulfur, may have minor roles. The action of some alloying elements can be beneficial, neutral, or detrimental, depending upon whether localized or uniform corrosion is being considered and whether the steel is fully, partially, or intermittently immersed. A large program of work between a number of research laboratories in Europe was carried out over an extended period to study the influence of alloying elements on corrosion of low alloy steel<sup>11</sup> and the main findings, which are summarized in **Table 3**, are still relevant.

From a consideration of **Table 3**, steel containing copper and phosphorus might be chosen for its resistance to corrosion in the critical tidal and splash zone.

**Figure 4** Directionality in microstructure after mechanical deformation. (a) 0.2% C steel after hot rolling showing banded carbide microstructure. (b) 0.6% C steel after cold wire drawing showing highly deformed grain structure. Reproduced by kind permission of Cochrane, R. F. University of Leeds and the DoITPoMS Micrograph Library ([www.doitpoms.ac.uk](http://www.doitpoms.ac.uk)).

**Table 2** Corrosion rates of mild steels in seawater, total immersion for 203 days at Plymouth

Type of steel <sup>a</sup>	Analysis (%)				Average general penetration (mm year <sup>-1</sup> )
	C	Mn	P	S	
Basic Bessemer, rimming ordinary	0.05	0.64	0.06	0.02	0.143
High phosphorus	0.03	0.31	0.14	0.04	0.143
High phosphorus and sulfur	0.03	0.30	0.10	0.07	0.148
Open-hearth, rimming ordinary	0.13	0.33	0.03	0.03	0.143
From haematite pig	0.06	0.32	0.01	0.03	0.140
Open-hearth, killed ordinary	0.10	0.35	0.03	0.02	0.140
From haematite pig	0.11	0.34	0.01	0.03	0.136
Open-hearth, killed ordinary	0.22	0.71	0.03	0.03	0.143
From haematite pig	0.21	0.58	0.02	0.03	0.158

<sup>a</sup>The copper contents of the steels, which were supplied through the courtesy of l'Office Technique pour l'Utilisation de l'Acier (France), varied from 0.03 to 0.11%. The killed steels contained 0.04% Al and 0.1% Si.

However, in practice the sample-to-sample variation in corrosion rate is much greater than the difference between various alloy steels, so it is improbable that low-alloy steels will corrode more slowly than mild steel in most practical environments. This conclusion was supported by Forgeson *et al.* in the 1960s who concluded from extensive tests in fresh and salt waters of the Panama Canal Zone that: “proprietary low-alloy steels were not in general more resistant to underwater corrosion than the mild unalloyed carbon steel.”<sup>12</sup> In any case, it is rare to expose unprotected steel in this way without a reliable corrosion control method such as cathodic protection also being applied.

The generally negligible effects of alloying additions on the corrosion of low alloy steels under immersed conditions were also reported in historic work from the 1930s to 1950s by the former British Iron and Steel Research Association (BISRA) in the UK<sup>13</sup> and the National Bureau of Standards (NBS) in the USA.<sup>14</sup> The latter work was rather extensive and involved ten varieties of steel (as well as cast irons), which were buried in 15 typical American soils from 1937 to 1950. The results showed that, with few exceptions, the corrosion of low-alloy steels containing copper, nickel, and molybdenum in various combinations did not differ by more than 20% from that of ordinary carbon steel. The main exception was chromium, where additions of 2% or 5% of chromium did increase the corrosion resistance somewhat, as is indicated in Figure 5.

### 3.01.2 Electrochemistry

#### 3.01.2.1 Thermodynamics

Iron is a relatively active element whose domain of stability resides completely below that of the domain of stability for water. Thus, in principle, iron can evolve hydrogen from aqueous solutions at all pH, Figure 6. In practice, hydrogen evolution occurs readily only at low pH (i.e., below ~pH 3); at higher pH, although it

**Figure 5** Effect of chromium content on the corrosion of buried steel. Reproduced from Romanoff, M. Underground Corrosion, National Bureau of Standards Circular 579, US Government Printing Office, Washington, 1957.

is thermodynamically possible, hydrogen evolution is very slow at ordinary temperatures due to the low driving force and sluggish kinetics. At intermediate pH, iron passivates and at higher pH iron may dissolve as the ferroate oxyanion, although this reaction is sluggish and passive iron is practically stable to pH 13 and above (e.g., in concrete). Iron corrodes readily, therefore, in near-neutral oxidizing environments, including: the atmosphere, natural waters in equilibrium with atmospheric carbon dioxide and seawater, however, the rate of corrosion in oxygen-free neutral waters is much less and controlled by the stability of the passive film. Iron is more active than elements such as nickel, copper, cobalt, etc. but is more noble than zinc, aluminum, magnesium, etc. Thus, the latter elements are, in practice, important for use as sacrificial anodes for the cathodic protection of steel. Apart from a few exceptions in specific circumstances, minor variations in the composition of steel generally have minimal effect on the overall electrochemistry and, hence, the corrosion rates.

Iron has two stable oxidation states: ferrous (+2) and ferric (+3). Typically, divalent ferrous species are

considerably more soluble in aqueous solution than the trivalent ferric species, which have significant solubility only at low and high pH. The oxides and hydroxides of iron are complex and interrelated crystallographically; furthermore, many of the ferric

oxides undergo reductive dissolution to soluble ferrous species, such as the  $\text{Fe}(\text{OH})^+$  ion. **Figures 6 and 7** show a Pourbaix diagram for the limits of stability of soluble iron species at a concentration of  $10^{-5}$  M.

**Figure 6** Pourbaix diagram for iron with soluble species at concentration of  $10^{-5}$  M, and with the most frequent stable oxide species present. Calculated using HSC version 6.12 thermochemical modelling software, Outotec, Finland.

**Figure 7** Pourbaix diagram for soluble species only (i.e., excluding solid species) at a concentration of  $10^{-5}$  M. Calculated using HSC version 6.12 thermochemical modelling software, Outotec, Finland.

**3.01.2.2 Anodic Dissolution****3.01.2.2.1 Oxygen-free (deaerated) conditions**

The mechanism for the dissolution of iron, whether in aerated or deaerated conditions, varies as a function of pH and, despite extensive investigation by Bockris,<sup>15–18</sup> Drazic,<sup>19,20</sup> Lorenz,<sup>21,22</sup> Hackerman,<sup>23</sup> and others, is still not entirely resolved. One of the complications is that the mechanism is greatly influenced by a number of factors including the nature of the anions present in solution. The most commonly accepted generic reaction sequence in deaerated acid conditions is due to Bockris, Drazic, and Despic<sup>17</sup> where a reaction order of  $\sim 1$  with respect to hydroxide ion concentration (i.e., the kinetics are a function of pH) was determined for the anodic dissolution of iron at pH < 4. This broadly fits the following reaction sequence:

Thus, adsorption of water initially occurs onto the iron surface together with the first single electron transfer step giving rise to a transient intermediate ( $\text{FeOH}_{\text{ads}}$ ). The second electron transfer step, giving rise to the stable  $\text{Fe}(+2)$  oxidation state, occurs subsequently and is rate determining. In near neutral solution ( $4 < \text{pH} < 9$ ) this sequence is modified slightly<sup>24</sup> and after reaction [2] above, the following sequence holds:

In both cases, the overall reaction is the familiar:

In alkaline solution ( $\text{pH} > 9$ ), and in the absence of oxygen, passivation of the iron surface occurs after reaction [4] with the initial formation of ferrous hydroxide, reactions [7] below and subsequent oxidation to magnetite:

Finally, strong alkali ferrous hydroxide can chemically dissolve as the dihypoferrite anion that is in equilibrium with the hypoferrite (ferroate) anion:

**3.01.2.2.2 Oxygen containing (aerated) conditions**

When dissolved oxygen is present, ferrous species are unstable to further oxidation in solution to ferric species, which have considerably lower solubility products and are liable to precipitation giving rise to the familiar rust corrosion product. Thus, in aerated near-neutral to acid conditions, ferrous ions are oxidized by dissolved oxygen in solution, with  $\text{FeO}(\text{OH})$  as the end product (other oxides/hydroxides are possible):

Any formed ferric oxide will immediately precipitate giving rise to the familiar brown staining that denotes rusting. If precipitation occurs close to the metal surface (as is likely in aerated solution), oxide will tend to build up on the iron, although this will not be in a coherent and impermeable manner. Hence, rust layers formed in this way can only provide a diffusion restriction for the corrosion of iron and steel and do not result in passivation.

In alkaline environments at  $\text{pH} > 9$ , passive ferrous hydroxide and magnetite (in which 1/3 of the iron atoms are in the ferrous state and 2/3 ferric) are also susceptible to further oxidation to ferric hydroxide:

However, in these cases, the reaction occurs in the solid state and the iron remains passive with the advantage that ferric hydroxide has a greater thermodynamic stability range. Note that the oxidation of ferrous hydroxide and magnetite to ferric hydroxide is reversible and, hence, the passive film is unstable to electrochemical reduction.

**3.01.2.2.3 Anion adsorption effects on the mechanism of dissolution**

As key steps in the anodic dissolution mechanism for iron involve the adsorption of water or hydroxyl ions,

it is evident that the presence of other anions that compete for adsorption will influence the concentration of the adsorbed hydroxyl intermediate and, in consequence, the corrosion rate. For example, the effect of halide ions on the corrosion rate of iron in acid media has been known for over 80 years.<sup>25</sup> Although, it is widely assumed that halides are uniformly aggressive (i.e., increase corrosion rates), this is not universally the case, and at low-to-intermediate concentrations in acid, they can act as effective inhibitors. For example, iodide ions inhibit corrosion of mild steel in 0.5 M H<sub>2</sub>SO<sub>4</sub> at concentrations less than  $\sim 10^{-2}$  M with an inhibition efficiency (i.e., percentage reduction in corrosion rate) of up to 90%.<sup>26</sup> The effectiveness of inhibition decreases in the order: I<sup>-</sup>, Br<sup>-</sup>, and Cl<sup>-</sup>, which is consistent with the adsorption efficiency of the anions and confirmed by electrochemical impedance spectroscopy measurements of surface capacitance. Species that are only weakly absorbing (such as perchlorate) have no significant effect on the corrosion rate. Of course, a distinction here has to be made between species that interfere directly with the anodic dissolution process and species that interfere with a cathodic reaction such as hydrogen evolution. A large class of organic inhibitors for corrosion in acids (e.g., pickling inhibitors) act by adsorbing onto the surface of the steel and, hence, block either or both of the electrochemical reactions.<sup>27</sup>

### 3.01.2.3 Passivity

#### 3.01.2.3.1 Passive oxide films

The phenomenon of passivity was probably first recorded by James Keir in 1790 on the exposure of iron to concentrated nitric acid.<sup>28</sup> He noticed that if the concentration of nitric acid was sufficiently high, gas evolution appeared to cease and the iron appeared to be in a quiescent state. This 'passive' state of iron was later explained by Michael Faraday in 1836 and, given the undeveloped state of knowledge at the time, his comments are immensely prescient<sup>29</sup>:

... my impression is that the surface of the metal is oxidised or else that the superficial particles of the metal are in such relation to the oxygen of the electrolyte as to be equivalent to oxidation ...

Passivity is now known to be caused by the formation of an oxidized species on a metal surface under the correct conditions of potential and pH. Thus, on formation of a more-or-less thermodynamically stable, compact, and continuous film on a metal surface,

the kinetic processes involved in corrosion (e.g., electron and ion charge transfer, diffusion of reacting species, etc.) are slowed by many orders of magnitude. For ferrous alloys, and as indicated above, passivity occurs at intermediate pH and at sufficiently high oxidizing potentials and results in the formation of an oxide film. The literature on passivity in general, and on passivity of iron in particular, is extensive. Of interest are the mechanisms of passive oxide film formation, its structure and composition, the long-term stability of the film, and its local breakdown in the presence of species such as chloride ions and others (i.e., pitting).

Passive iron oxide is thermodynamically stable at sufficiently high potentials. Thus, the passive film on iron can itself participate in the corrosion process as a cathodic reactant, and is consequently destroyed in the process. In this way the passivity of iron is fundamentally more unstable than, for example, that of chromium or of aluminum. Also, unlike other passive films which are generally insulating, the passive oxide on iron (e.g., magnetite) is an electronically conducting n-type semiconductor<sup>30</sup> and forms an effective electrode for, for example, oxygen reduction.

Regarding the nature of the film, it was historically proposed to consist of a Fe<sub>3</sub>O<sub>4</sub> inner layer with an outer layer of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>,<sup>31,32</sup> results that appeared to be consistent with electrochemical data. However, later Mössbauer studies demonstrated that the passive film contained only ferric species with no evidence of significant Fe<sup>2+</sup> present. Also, the films were likely to be microcrystalline or amorphous and did not appear to change structurally on drying in air.<sup>33,34</sup> For passive films formed on iron by anodic polarization in borate buffer solution at pH 8.4, the hydroxyl content of the film was shown by secondary ion mass spectrometry (SIMS) to be effectively zero,<sup>35</sup> thus confirming that the film was an oxide only and not a hydroxide.

A criticism of most research of this type is that it is necessarily carried out *ex situ* (i.e., the passive film was formed in solution the sample was removed and then analyzed elsewhere). Truly *in situ* measurements of the passive film structure were only achieved in the 1990s by use of X-ray absorption near edge fine structure<sup>36</sup> and scanning tunneling microscopy,<sup>37</sup> which showed that the film is either amorphous or a crystalline spinel (i.e., similar to Fe<sub>3</sub>O<sub>4</sub> and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>), thus confirming the previous results but leaving open the question of precisely which structure is correct.

The controversy on the structure of passive iron oxide appears now to have been solved by Toney *et al.* using careful *in situ* and *ex situ* synchrotron X-ray

diffraction measurements on high purity iron.<sup>38</sup> This confirmed that the diffraction peaks were similar to spinel, but that the structure factors did not conform to either  $\text{Fe}_3\text{O}_4$  or  $\gamma\text{-Fe}_2\text{O}_3$ , or indeed any other known oxide or hydroxide of iron. Full X-ray structure refinement determined that the passive film consists of a nano-crystalline spinel unit cell (containing 32 oxide anions) with cation occupancy of  $\sim 80\%$  for octahedral sites,  $66\%$  for tetrahedral sites, and with  $\sim 12\%$  of cations occupying octahedral interstitial sites. Note that despite the superficial similarities to both the magnetite ( $\text{Fe}_3\text{O}_4$ ) and maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) structures, it is a distinctly different material, termed the LAMM phase. Later work by the same authors, using a molecular modeling approach, has indicated that the LAMM phase is metastable.<sup>39</sup> However, this may not be so surprising considering that the film is formed under nonequilibrium conditions and, since it is thin, surface and interfacial free energies will dominate over the free energy of the macroscopic phase.

Similar experimental problems exist for determining the mechanism for passive oxide film growth. This is commonly assumed to occur via ion conduction caused by the electric field between the metal and the electrolyte. A clever experiment using isotopically labeled reagents studied the film formed after sequential anodizing of iron in ordinary and  $^{18}\text{O}$  enriched water, using SIMS to monitor the  $^{18}\text{O}/^{16}\text{O}$  ratio.<sup>35</sup> The results were consistent with the majority

transport mechanism during film growth consisting of inward oxygen ion transport in the lattice; however, some  $^{18}\text{O}$  was detected at the interface indicating that some short-circuit diffusion paths exist in the structure, presumably at crystalline boundaries.

### 3.01.2.3.2 Nonoxide passive films

In the strict sense, passivity relates to the process of oxidation leading to a solid corrosion product that forms in such a way (i.e., thermodynamically, or at least kinetically, stable, continuous, without substantive defects, relatively insoluble, and generally resistant to further oxidation or reduction) as to provide a significantly protective film. This definition does not have anything to say about the chemical nature of the passive film. Indeed, although passive oxide films are by far the most important type, passive films may also consist of sulfides, chlorides, etc.

In sulfide environments, for example, steel may passivate by the formation of an iron sulfide film, **Figure 8**. However, this film has distinctly different properties to passive oxides.<sup>40</sup> Firstly, the initially formed film is nonstoichiometric ( $\text{FeS}_{1-x}$ ) and, like  $\text{Fe}_3\text{O}_4$  (but unlike  $\text{FeO}(\text{OH})$ ) is electronically conducting and is an excellent cathode, especially for the hydrogen evolution reaction. Secondly, the film is unstable to further oxidation to  $\text{FeO}(\text{OH})$  and  $\text{FeS}_2$ , which, due to volume expansion, disrupts the film and results in damage, including cracking. Cracks and

**Figure 8** Pourbaix diagram for iron and sulfur at  $10^{-5}$  M metal ion and  $10^{-3}$  M sulfur species. Calculated using HSC version 6.12 thermochemical modelling software, Outotec, Finland.

other defects in the sulfide film effectively result in small local anodes that, when coupled to the large efficient external cathode (the remnant sulfide film), causes severe localized (pitting) corrosion.

Other forms of corrosion that result in the formation of surface films with significant protective properties are often the result not of direct oxidation to a solid species, but rather by precipitation of an insoluble salt that covers the metal surface, for example, iron phosphate. In the strict sense, this is not 'passivity,' although it is often described as such, particularly, if the end result (a greatly reduced corrosion rate and a tendency for corrosion to occur in a localized manner) is similar. In some cases, however, it is unclear whether the film forms by direct oxidation or by precipitation. For example, a protective ferrous sulfate film forms during corrosion of steel in concentrated sulfuric acid,<sup>41</sup> since iron sulfate is relatively insoluble in this environment. Also, corrosion of steel in environments containing dissolved carbon dioxide (so-called 'sweet' corrosion in the oil and gas industry) can result in a protective film of ferrous carbonate under some conditions.<sup>42</sup> Such films may either form by precipitation (salt films) or may form by direct oxidation to a solid product where the solubility of the species is extremely low. However, whether this is really passivity or not is ultimately a matter of semantics.

### 3.01.2.4 Cathodic Reactions

#### 3.01.2.4.1 Hydrogen evolution reaction

The hydrogen evolution reaction is one of the most studied electrochemical processes partly due to its technological interest but also due to the relative ease of investigation (one only needs to place some zinc in sulfuric acid to observe hydrogen bubbles being produced). The mechanism for hydrogen evolution on iron involves initial discharge of hydrogen ions on the metal surface with corresponding adsorption of a hydrogen atom followed by the rate determining reaction<sup>43</sup>: most commonly, chemical desorption of adsorbed hydrogen [14a] or, at high overpotential, electrochemical desorption of adsorbed hydrogen [14b]:

Chemical desorption of adsorbed hydrogen [14a] is a potential independent reaction and consequently, the surface coverage of hydrogen may build up to a high equivalent thermodynamic fugacity (i.e., equivalent pressure or chemical activity). This has the important consequence that the atomic hydrogen has sufficient residence time on the metal surface to enter the metal lattice (and cause embrittlement, hydrogen induced cracking, and other related phenomena) before combining to give molecular hydrogen that leaves the surface.

#### 3.01.2.4.2 Oxygen reduction reaction

The oxygen reduction reaction on iron is important in all aerated conditions and particularly so in near-neutral to alkaline solutions where, in the majority of technologically important corrosion problems, oxygen is the dominant cathodic reactant. Unlike reduction of hydrogen ions, which is a 2-electron process that occurs via two successive single electron transfer reactions, the mechanism for the reduction of dissolved oxygen is intrinsically more complex due to the overall required transfer of four electrons. The initial step for the reduction of oxygen is generally believed to involve one or both of a superoxide or a peroxide intermediate species. However, hydrogen peroxide once formed is easily reduced in a 2-electron process that cleaves the central O–O bond.

The overall reaction for oxygen reduction differs according to whether the iron is passive (i.e., the reduction process occurs on an oxide or hydroxide surface) or whether the surface of iron is oxide-free (i.e., bare iron). An extensive investigation of the oxygen reduction reaction on iron in neutral solution was carried out by Jovancicevic.<sup>44</sup> For passive iron, the reaction scheme that best fits the observations involves rate determining adsorption of oxygen followed by stepwise reduction of the adsorbed intermediate initially to an adsorbed superoxide species ( $\text{O}_2\text{H}$ ) then to peroxide ion ( $\text{O}_2\text{H}^-$ ). This reacts immediately in water to form hydrogen peroxide, which may be detected in solution using a rotating ring disc electrode, and which is relatively easily reduced to hydroxide:

The overall reaction being the familiar:

On bare iron, the situation differs in that no hydrogen peroxide species are detectable in solution; also, the kinetics of reduction are slower. In this case, therefore, the partly reduced intermediaries are expected to exist as adsorbed species on the metal surface. The rate-determining step is, in this case, consistent with adsorption and reduction of oxygen to an adsorbed superoxide species ( $\text{O}_2^-$ ):

After this, the sequence is unclear but one that is consistent involves stepwise reduction, via an adsorbed peroxide intermediate, to hydroxide:

### 3.01.2.5 Corrosion in Aqueous Environments

#### 3.01.2.5.1 Anode and cathode separation

During corrosion, the local electrochemical potential at an anode is different from that at a cathode. Also, the local electrochemical reactions at anodes and cathodes result in significant chemical changes in their vicinity that encourage and maintain their spatial separation. Furthermore, the potential difference in solution gives rise to a voltage gradient, which attracts oppositely charged ions (or repels similarly charged ions), a process known as electro-migration. Additionally, there is the requirement for electro-neutrality in the electrolyte (by which is meant that an anion cannot exist in solution without a corresponding cation). The overall process for corrosion of iron with oxygen as the cathodic reaction is shown schematically in Figure 9, with migration and diffusion of ions carrying the flow of current.

#### 3.01.2.5.2 Mass transport

For many, if not the majority, of the technical applications of carbon steel, the aqueous corrosion rate is controlled by the diffusion of reacting oxygen to the metal surface and/or the diffusion of dissolved species away from the surface. Under these conditions, mass transport in the solution becomes critical. In general, mass transport occurs by three fundamental processes:

**Figure 9** Schematic diagram showing spatial separation of anode from cathode with corresponding migration of ions in solution.

- Diffusion (i.e., movement under a concentration gradient)
- Migration (i.e., movement under an electric field gradient)
- Convection (i.e., natural or forced solution flow)

The total flux of reactant to a surface or interface (i.e., the total mass transport) is obtained simply by addition of the components of diffusion and migration to that of convection:

$$\text{Flux} = \text{Diffusional} + \text{Migrational} + \text{Convective}$$

In all flow conditions, a region of fluid exists adjacent to the surface of the electrode in which no convection occurs and only diffusion and migration occur; this is called the boundary layer, and may be equated with the diffusion distance in Fick's Law. Generally, as the convection rate increases, the boundary layer is compressed and reduced in extent and, hence, the overall rate of mass transport increases.

#### 3.01.2.5.3 Effect of flow rate on corrosion

For corroding systems, under mass transport control, the flux of species to a surface where the rate-controlling reaction is occurring is described in the steady-state by Fick's first Law. This flux may be also measured electrochemically by the limiting current for that reaction (e.g., oxygen reduction). In this way, a mass transfer coefficient,  $k$ , may be defined by:

$$k = \frac{i_{\text{lim}}}{nFC_b} \quad [25]$$

where:  $i_{\text{lim}}$  is the limiting current density for a cathodic reaction,  $C_b$  is the bulk concentration of cathodic reactant,  $F$  is Faraday's constant and  $n$  is the number of electrons transferred in the reaction. For a corrosion process whose rate is controlled by mass transfer of cathodic reactant, for example carbon steel in neutral, oxygen-containing solutions,

knowledge of the mass transfer coefficient,  $k$ , enables prediction of corrosion rate.

Measurement of the diffusion flux may be carried out using standard electrochemical techniques as a function of fluid flow rate, either via rotating electrode systems, or via electrodes placed in flow channels. For laminar flow, the analytical solution predicts that the limiting current ( $i_{\text{lim}}$ ) at a rotating electrode is proportional to the concentration of reacting species in solution and the square root of the rotation speed, the Levich equation<sup>45</sup>:

$$i_{\text{lim}} = A C \omega^{0.5}$$

where:  $\omega$  is the angular rotation rate of the electrode (radians  $\text{s}^{-1}$ ),  $C$  is the concentration of reacting species, and  $A$  is a constant that depends on the fluid properties and diffusion rate of the reacting species. Thus, if a plot of  $i_{\text{lim}}$  v.  $\omega^{0.5}$  is a straight line, then the reaction is mass-transport controlled and the diffusion coefficient for the reacting species can be obtained from the slope of the straight line. This general kind of relationship holds for fluid flow in more complex geometries, including turbulent flow, where analytical solutions are not possible. Hence,

experimental analogies for particular situations must be developed, commonly in terms of dimensionless parameters such as the Sherwood number (related to mass transport), the Reynold number (related to the fluid flow rate), and the Schmidt number (related to the fluid properties). For more detailed information on corrosion in flowing systems, the reader is referred to the relevant chapter of this book.

### 3.01.3 Corrosion Processes

Some of the technically more important corrosion processes for steel are summarized in this section. Note, however, that this is not intended as a comprehensive treatment and more detailed descriptions of these processes (both in general and in specific situations) will be found in the relevant chapters elsewhere in this book.

#### 3.01.3.1 Corrosion Products

For general information, common compounds associated with the corrosion of steel are listed in [Table 4](#).<sup>46</sup>

**Table 4** Corrosion products formed on carbon steel in various environments

Compound	Comments
<i>Oxides:</i>	
FeO (wüstite)	Formed during high temperature oxidation, present in millscale with $\text{Fe}_2\text{O}_3$ and $\text{Fe}_3\text{O}_4$
$\alpha\text{-Fe}_2\text{O}_3$ (hematite)	Iron ore mineral, also formed at elevated temperatures
$\text{Fe}_3\text{O}_4$ (magnetite)	Corrosion product formed in reducing aqueous conditions
$\gamma\text{-Fe}_2\text{O}_3$ (maghemite)	Oxidized form of magnetite and with the same crystal structure
<i>Oxy-hydroxides:</i>	
$\alpha\text{-FeO(OH)}$ (goethite)	Stable mineral, commonly found in nature
$\gamma\text{-FeO(OH)}$ (lepidocrocite)	Metastable phase, formed during atmospheric corrosion
$\beta\text{-FeO(OH,Cl)}$ (akaganéite)	Formed during corrosion in seawater – characteristic orange color
$\text{Fe}_5\text{O}_3(\text{OH})_9$ (ferrihydrite)	Common iron mineral: metastable to hematite and goethite
<i>Hydroxides:</i>	
$\text{Fe(OH)}_2$ (ferrous hydroxide)	Intermediate corrosion product formed under reducing conditions
$\text{Fe(OH)}_3$ (ferric hydroxide)	Hydrated iron oxy-hydroxide, more properly written as: $\text{FeO(OH)} \cdot \text{H}_2\text{O}$
<i>Sulfides:</i>	
$\text{FeS}_{1-x}$ (mackinawite)	Anion deficient FeS (troilite) formed during microbially influenced corrosion
$\text{Fe}_{1-x}\text{S}$ (pyrrhotite)	Iron sulfide mineral, cation deficient form of FeS (troilite)
$\text{FeS}_2$ (pyrite)	Iron sulfide mineral, known as ‘fool’s gold’
<i>Carbonates:</i>	
$\text{FeCO}_3$ (siderite)	Corrosion product that forms as a protective film in some forms of ‘sweet’ corrosion at high $\text{CO}_2$ partial pressures; occasionally also found as part of the corrosion product layer on archaeological iron objects after long-term burial
<i>Phosphates:</i>	
$3\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$ (vivianite)	Occasionally found within the corrosion product layer on archaeological iron objects after long-term burial in strongly anaerobic, typically water-logged, environments
<i>Green rusts:</i>	
$[\text{Fe}_3^{2+} \text{Fe}^{3+} (\text{OH})_8]^+ [\text{Cl} \cdot \text{H}_2\text{O}]^-$	Series of corrosion products that comprise mixed ferrous/ferric species together with incorporated anions, in particular: carbonates, sulfates and chlorides

### 3.01.3.2 Aqueous Corrosion

#### 3.01.3.2.1 General corrosion

In the absence of inhibiting species, carbon and low alloy steel are not passive in most aqueous environments at pH less than  $\sim 9$ . Thus, for the majority of natural environments likely to be encountered in service, steel will undergo general corrosion. It is important to note that the term 'general corrosion' does not imply uniform thickness loss across a corroding surface rather it defines an active corrosion process that occurs in the absence of a passive film.

In practice, the general corrosion of uncoated steel in high conductivity media such as seawater will generally lead to an overall macroscopic roughening of the surface. This is exacerbated by the presence of surface-breaking second phase particles, the most important of which are sulfide inclusions that are always present in steels. For example, partial dissolution of sulfide inclusions results in aqueous sulfide species and the possible formation of adjacent iron sulfide films resulting in a surface electrochemical heterogeneity.<sup>47–49</sup> Hence, heterogeneity in the

corrosion rate is developed across the material surface eventually resulting in variations in the thickness loss over the surface.

In low conductivity environments such as natural waters, the resistivity of the electrolyte is sufficiently large that the spatial separation of anodes and cathodes is greatly reduced. This tends to result in the localization of corrosion to specific regions of the surface with associated local precipitation of corrosion product giving the appearance of small protuberances. Such corrosion is often called tuberculation corrosion and can result in local attack underneath the precipitated corrosion product,<sup>50</sup> **Figure 10**. Although giving the appearance of pitting, the mechanism is in essence an extremely localized form of general corrosion combined with differential aeration corrosion. In the fullness of time, such regions will tend to merge together giving a macroscopically roughened surface.

**Figure 10** Tuberculation corrosion of steel; corrosion is localized beneath rust protuberances (known as tubercles).

#### 3.01.3.2.2 Concentration cell corrosion: Differential aeration

Where differences in concentration of an electrochemically active species are present in an environment then corrosion is likely to result. For example, for a buried structure, the local oxygen concentration will vary according to whether the soil is well-aerated or not, with the degree of aeration also varying as a function of soil depth. Thus, cathodes are likely to be localized at regions of relatively higher oxygen availability with anodes localized in regions of lower oxygen content. This is effectively a corrosion cell that is driven by a spatial variation in oxygen concentration in the environment (and is thus known as a concentration cell). Localization of the corrosion reactions can be readily demonstrated in a droplet of salt water on steel by the use of indicators that show the high pH generated at a cathode (e.g., by use of phenolphthalein, which turns pink) and the ferrous ions generated at an anode (e.g., by use of ferricyanide, which turns blue), **Figure 11**.

**Figure 11** Corrosion in a salt water droplet showing the cathodic reaction localized at the droplet periphery (due to oxygen availability) and the anodic reaction localized in the droplet centre (due to oxygen depletion).

Differential aeration is an important factor in many corrosion processes where local oxygen depletion is present. For example, corrosion that is localized underneath deposits, and between mating surfaces, etc., is almost always caused by a differential aeration mechanism. In general, those localities that have a plentiful supply of oxygen will become cathodes with anodes occurring in regions of oxygen depletion.

### 3.01.3.2.3 *Pitting and crevice corrosion*

At alkaline pH and in the region where passivity of carbon steel is possible, then classical pitting and crevice corrosion mechanisms, that is, those involving local breakdown of a passive film, are possible. Localized corrosion may also result where the surface has been passivated by other means, such as oxidizing inhibitors (e.g., nitrite, etc.) or in sulfide environments.

For the pitting of pure iron in neutral electrolytes with a passive oxide film, pit initiation was found to be associated with a stage in the development of the film corresponding to a particular film thickness. This was found to be potential independent but dependent on the halide ion type (i.e.,  $\text{Cl}^-$  or  $\text{Br}^-$ ) and concentration as well as the anodic charge passed prior to pitting.<sup>51,52</sup> No incorporation of halide into the passive film was observed, which is in stark contrast to stainless steel, where halide ions do incorporate into the chromium passive film.<sup>53</sup> This is an evidence of the structural stability of the passive film on iron (which once formed is relatively stable) compared with the passive film on Fe–Cr alloys (which changes with time in accommodation to the environment). Note, of course, that passive iron oxide is unstable to reductive dissolution, which is not the case with stainless steel and is one of the reasons for the improved passivity of stainless alloys. Overall, iron (at a given pH in a given supporting electrolyte) appears to be susceptible to halide-induced pitting, if and only if, the passive oxide has reached a certain critical stage of growth.

Pitting can be generally prevented if there are sufficient alternative anion species present (e.g., nitrate, sulfate, and hydroxide). Thus, pitting generally is only feasible if the ratio of chloride to other anions exceeds certain critical values, which are environment, pH, and temperature dependent; for example, the chloride-to-hydroxide ratio for pitting corrosion of steel reinforcement in concrete.<sup>54,55</sup> Also, for a propagating pit, the chemistry must be consistent with the active regime of corrosion as indicated in the Pourbaix diagram. Given that the cathode area is large while that of the anode is small, the anodic current density

(and hence the local rate of dissolution) in a pit must necessarily be high.

Pitting of steel also occurs in the presence of passive sulfide films such as mackinawite ( $\text{FeS}_{1-x}$ ). Sulfide films are inherently unstable to oxidation with consequent disruption that results in the generation of defects and flaws in the film.<sup>56</sup> Since the film is an excellent cathode, anodes localize at the defects where the substrate is exposed thus resulting in severe local pitting.

Pitting and crevice corrosion are therefore associated with local development of chemical heterogeneity on the surface at the pit site. Furthermore, their occluded geometry, once formed, tends to maintain the solution at a significantly different local chemistry than the environment. This form of localized corrosion is much more likely to occur in stagnant conditions where the development of diffusion-driven solution heterogeneity over the metal surface is encouraged. Conversely, under flowing conditions, local diffusion-driven chemical changes cannot be maintained so effectively and pitting is less likely. Pumps and valves that operate intermittently with long periods of nonoperation are particularly prone to internal pitting and crevice corrosion.

### 3.01.3.2.4 *Galvanic corrosion*

Although the electrochemical series forms an outline guide for the tendency or not for galvanic corrosion, it is important to note that the position of alloys in the series is altered in specific environments and a galvanic series developed for the environment should therefore be consulted. Galvanic series for metals and alloys in seawater and potable waters are well-known and easily available.<sup>57</sup>

There are two necessary requirements for galvanic corrosion to occur: firstly, electrical connection to another electronically conducting material of a different electrochemical potential (commonly a metal, although conducting films such as magnetite and mackinawite as well as graphite can also act as electrodes) and secondly connection through the electrolyte solution (in order to permit ionic current to flow). Galvanic corrosion can also occur in a macroscopic sense between components differing materials, but may also occur microscopically at preexisting metallurgical features in the steel or, more commonly, where metal ions of a more noble element are present in solution and plate out locally on the steel surface. Thus, where copper ions plate out onto steel, for example from corrosion of a brass component elsewhere in the system, then local galvanic corrosion will initiate at such locations.

### 3.01.3.2.5 Flow-assisted corrosion (FAC)

The phenomenon of flow-assisted (or flow-accelerated) corrosion (FAC) is of fundamental importance and occurs particularly in high performance boilers and heat exchangers such as are used in power generating facilities (both conventional and nuclear), but also elsewhere.<sup>58</sup> The general mechanism of FAC is not limited to steel and involves the removal of a protective corrosion product, generally by dissolution, in a flowing environment. The process has long been known to occur in high flow rate systems, for example in copper alloy condenser tubing where the relatively soft and poorly adherent protective surface films are stripped from the surface by the shear stress across the boundary layer between the pipe wall and the moving turbulent fluid.

For carbon steel, the latter mechanism does not operate as the protective magnetite layer adheres strongly to the substrate. However, in common with all minerals, iron oxides are sparingly soluble in water and FAC involves the local or general thinning of the protective oxide film that forms on carbon steel in high temperature water. However, oxides where iron is entirely in the ferric (+3) oxidation state are considerably less soluble than magnetite as can be seen from Table 5.

In traditional boiler water treatment, the dissolved oxygen concentration is kept as low as possible (a few parts per billion, ppb) where magnetite is the stable oxide phase. It is thus susceptible to enhanced dissolution under high flow rate conditions. This leads both to unwanted deposition of oxide elsewhere in the system but, more importantly, enhanced corrosion of steel and often unexpected failures with typical scalloped surfaces.<sup>59</sup> However, if the oxygen concentration is controlled at a slightly higher level hematite becomes the stable phase. This is

advantageous as it is considerably less soluble than magnetite and, hence, much more resistant to flow-accelerated corrosion (FAC).

### 3.01.3.2.6 Erosion-corrosion

In the presence of two-phase flow in solution (i.e., solid particles, slurries, entrained gas, etc.) enhanced corrosion will generally occur due to a number of mechanisms including: increased mass transport of reacting species and impact of the 2nd phase onto the surface, see for example.<sup>60</sup> The latter process is the most important in causing erosion-corrosion as its effect on the protective surface film is critical. Thus, protective films may be thinned by abrasion or removed altogether causing rapid corrosion of the underlying material. This process is particularly prevalent where sharp changes in flow direction (e.g., pipe bends, etc.) or flow velocity (e.g., valves and chokes, etc.) occur. Careful design of plant components can minimize this form of attack.

### 3.01.3.3 Environmentally Assisted Cracking

#### 3.01.3.3.1 Environments

Carbon steel is susceptible to stress corrosion cracking in a range of environments, often where it shows passivity or marginal passivity. These include anhydrous liquid ammonia, nitrate/nitrite, strong alkali and in carbonate/bicarbonate systems. Stresses in the steel can either arise from externally applied forces or be the result of processing, deformation, welding, etc. giving rise to a residual stress that is present at all times.

Historically the most important of these processes was caustic cracking prevalent in low-to-medium pressure riveted steel boilers. In such systems boiler waters that were traditionally dosed with carbonate or bicarbonate for pH control lost CO<sub>2</sub> to the steam resulting in a gradual increase in pH. Although in well-controlled systems, the bulk pH would be maintained within correct limits, local concentration in crevices or under deposits could give rise to a strongly alkaline region that initiated intergranular stress corrosion.<sup>61</sup> The phenomenon is not restricted to boilers but can occur in any system that handles strong alkali, for example during purification of bauxite via the Bayer process<sup>62</sup> or in Kraft process paper digesters.<sup>63</sup> The morphology of caustic cracking is intergranular with a lower limit for cracking of carbon steel in the range 1–5% NaOH (additions of nickel improve resistance). Cracking is observed to be potential dependent<sup>64</sup> occurring only in the passive region

**Table 5** Solubility products for various iron oxides

Reaction	Solubility product at 25°C	Solubility product at 300°C
$\text{Fe}(\text{OH})_2 \rightleftharpoons \text{Fe}^{2+} + 2\text{OH}^-$	$10^{-15.04}$	$10^{-17.54}$
$\text{Fe}_3\text{O}_4 + \text{H}_2\text{O} \rightleftharpoons \text{Fe}^{2+} + 2\text{FeO}(\text{OH})$	$10^{-20.25}$	$10^{-21.40}$
$\text{Fe}_3\text{O}_4 + 4\text{H}_2\text{O} \rightleftharpoons \text{Fe}^{2+} + 2\text{Fe}^{3+} + 8\text{OH}^-$	$10^{-33.68}$	$10^{-33.59}$
$\text{Fe}(\text{OH})_3 \rightleftharpoons \text{Fe}^{3+} + 3\text{OH}^-$	$10^{-37.94}$	$10^{-36.87}$
$\text{FeO}(\text{OH}) + \text{H}_2\text{O} \rightleftharpoons \text{Fe}^{3+} + 3\text{OH}^-$	$10^{-41.58}$	$10^{-39.62}$
$\text{Fe}_2\text{O}_3 + 3\text{H}_2\text{O} \rightleftharpoons 2\text{Fe}^{3+} + 6\text{OH}^-$	$10^{-40.40}$	$10^{-39.68}$

and predominating in the region of the active-to-passive transition (i.e., from  $-800$  to  $-600$  mV vs. the Standard Hydrogen Electrode in 10% NaOH). Steels with lower carbon content appear to be more susceptible.<sup>65</sup> The failure mechanism is not thought to be associated with hydrogen embrittlement but is consistent with a slip dissolution model.<sup>66</sup>

Stress corrosion cracking of carbon and low alloy steels also occurs on buried structures under cathodic protection due to generation of alkalinity at coating defects by cathodic reduction. In aerated soil, carbon dioxide migrates to the cathodes in order to buffer the alkalinity thus producing the critical carbonate/bicarbonate environment. Failure surfaces are characterized by multiply branched intergranular cracks that tended to align along the principle stress axis of the pipe; fracture surfaces are often observed to be covered with magnetite.<sup>67</sup>

Transgranular stress corrosion cracking in anhydrous liquid ammonia is a separate phenomenon that unfortunately, because it was not understood, led to some catastrophic failures and loss of life.<sup>68</sup> The predominant risk factor for cracking in anhydrous ammonia is the presence of dissolved oxygen at  $>5$  ppm (or  $>1$  ppm in the presence of  $\text{CO}_2$ ). Cracking can be inhibited effectively provided that the ammonia contains more than 0.1% of water to encourage passivity of the steel.<sup>69</sup>

#### 3.01.3.3.2 Hydrogen embrittlement

Ferrite, like most body centered structures, has a high diffusivity and solubility for interstitial hydrogen in its lattice. Thus, carbon and low alloy steel are highly susceptible to hydrogen embrittlement and hydrogen-induced cracking. The former is caused by reduction in macroscopic ductility due to the presence of lattice hydrogen resulting in transgranular cleavage fracture, while the latter is due to the formation of hydrogen gas bubbles at extremely high pressure within the steel microstructure. There are numerous mechanistic models in the literature for the causes of hydrogen embrittlement and it is not clear whether a single mechanism prevails or whether several mechanisms coexist. A more detailed discussion of hydrogen embrittlement mechanisms and effects can be found elsewhere in the relevant chapter of this book.

#### 3.01.3.4 Microbiologically Influenced Corrosion

In nonsterile systems (i.e., generally at temperatures below  $\sim 60$ – $70^\circ\text{C}$ ) the growth and multiplication of a

wide range of microbial species is possible. For a microorganism to initially establish itself and then to grow and flourish, the environmental conditions must be favorable including a supply of a carbon food source and other trace essential nutrients (e.g., nitrogen, phosphorous, etc.) Many of the microbial species that have influence on the corrosion of carbon steel are anaerobic. Of these, sulfate reducing bacteria are the most frequently encountered. These metabolize oxidized sulfur species in their environment producing sulfide species in solution: that is,  $\text{H}_2\text{S}$ ,  $\text{HS}^-$ , or  $\text{S}^{2-}$ , depending on pH. These will form sulfide corrosion product films on steel that are nonprotective and unstable, resulting in severe and often local corrosion.<sup>70</sup>

Other problematic families of anaerobic bacteria include: the nitrate-reducers (that metabolize nitrite corrosion inhibitors, reducing their concentration), the organic acid producers (acetic and other acids can be aggressive to carbon steel depending on the environment), and iron oxidizers that metabolize ferrous ions resulting in unwanted deposition of ferric oxides. Anaerobic bacteria can survive (but not metabolize) in aerobic environments and can often tolerate low levels of oxygen. Thus, they may colonize benign environments in locations of low oxygen concentration (i.e., under deposits of corrosion product, dirt, etc., and under bio-films of oxygen-tolerant species), even though the overall environment may be relatively well-oxygenated.

#### 3.01.3.5 Aqueous Corrosion Protection

Although unprotected (bare) carbon and low alloys steel may be exposed without corrosion protection provided suitable allowances are made for corrosion losses during service, most steel is protected in some way. Methods available include: metallic coatings (e.g., galvanizing, electroplating, etc.), inorganic coatings (e.g., phosphate conversion coatings, etc.), organic coatings (i.e., paint coatings and linings) and cathodic protection. These topics are dealt with in detail elsewhere in this book and will not be considered further here.

#### 3.01.3.6 High Temperature Oxidation

Plain carbon steels cannot be used at temperatures close to the lower critical temperature for austenite formation, as the microstructure becomes unstable, with spheroidization of pearlite and graphitization of iron carbide. Also, significant grain growth and creep occurs. In practice, plain carbon steel has an effective

temperature limit of  $\sim 400\text{--}420^\circ\text{C}$ . For higher temperature service, low-alloy steels hardened by stable alloy carbides should be used.

Iron readily oxidizes at elevated temperatures in air (and other oxidizing environments) resulting in a relatively adherent layered scale. Above  $570^\circ\text{C}$  the ferrous oxide phase wüstite is stable and the oxide scale has three layers: a relatively thick inner layer of wüstite, a relatively thin intermediate layer of magnetite and a thin outer layer of hematite. The oxidation kinetics are controlled by diffusion of species through the scale thickness and are thus parabolic in nature. Wüstite has a large number of cation defects and is more properly written as  $\text{Fe}_{1-x}\text{O}$ . The oxide growth mechanism in wüstite is controlled by cation transport outwards,<sup>71</sup> resulting in relatively rapid oxidation rates. In view of this, the service temperature for carbon and low alloy steel should be below the formation temperature of wüstite.

Below  $\sim 570^\circ\text{C}$ , where wüstite is thermodynamically unstable, the oxide scale on iron contains an outer region of  $\text{Fe}_2\text{O}_3$  (hematite) with an inner region of  $\text{Fe}_3\text{O}_4$  (magnetite) adjacent to the metal. Since the transport processes (diffusion) through these phases is much less rapid, the oxidation rates are also less.<sup>72</sup> At these lower temperatures, the oxidation kinetics are not purely parabolic and are dependent on the surface preparation and degree of cold work present in the material; larger amounts of cold work resulting in more rapid oxidation. Plain carbon steel oxidizes somewhat (10–20%) more slowly than pure iron, which is almost certainly due to the presence of other alloying elements (e.g., silicon, manganese, and aluminum).<sup>72</sup> Below  $570^\circ\text{C}$ , increased carbon content generally results in an increased oxidation rate because the scale formed over carbide particles and especially pearlite colonies is finer with a higher iron diffusion rate.

The high temperature oxidation and corrosion of iron and steel is discussed in greater depth elsewhere in this book, to which the interested reader is referred.

### 3.01.4 Atmospheric Corrosion

#### 3.01.4.1 Environmental Influences

##### 3.01.4.1.1 Humidity

Relative humidity (RH) is defined as the ratio of partial pressure of water vapor to the saturated water vapor pressure at the same temperature. Thus, the RH is a thermodynamic quantity that is equivalent to the fugacity of water vapor in the gas phase.

Consequently, an RH of 100% defines a gas phase fugacity of 1, which is by definition in equilibrium with liquid phase water also at an activity of 1. In theory, therefore, atmospheric corrosion cannot occur at RH below 100% because no liquid water is present. However, in practice, water absorption readily occurs on bare metal surfaces at RH below 100% because, apart from gold, all metals are generally covered at standard conditions by hydrophilic thin oxide or hydroxide (passive) films.

Water adsorption on electropolished, uncontaminated surfaces as a function of RH from 0% to 80% was studied in the context of metrology in the precision weighing of stainless steel, silicon and platinum–iridium mass standards.<sup>73,74</sup> On these materials, water adsorption can be described well by a Brunauer–Emmett–Teller (BET) isotherm appropriate to multilayer adsorption on hydrophilic surfaces. On 20% Cr, 25%Ni stabilized stainless steel the water layer thickness was found to vary approximately linearly from 0% RH to 80% RH where it reached  $\sim 0.6$  nm, corresponding to about three monolayers of water.

Generally, the corrosion of metals in the atmospheric environment is possible if and only if there is sufficient water present on the metal surface to solvate the ions produced during corrosion reactions. This was first demonstrated by Vernon<sup>75</sup> in a series of classical experiments, some of which are summarized graphically in [Figure 12](#). He showed that rusting occurs at a low rate in pure air of less than 100% RH but that in the presence of minute concentrations of impurities, such as sulfur dioxide, serious rusting can occur without visible precipitation of moisture once the RH of the air rises above a critical and comparatively low value. This value depends to some extent upon the nature of the atmospheric pollution, but, when sulfur dioxide is present, it is in the region of 70–80%. Below the critical humidity, rusting is inappreciable, even in polluted air.

The results of Vernon have been confirmed many times. For example, more recent work has studied the integrity of carbon steel materials as a function of humidity in air at  $65^\circ\text{C}$ .<sup>76</sup> On clean, uncontaminated steel, the corrosion at and below 75% RH was negligible and consistent with a dry oxidation mechanism. However, at 85% and above, the corrosion rate rapidly increased, consistent with a critical RH for the onset of aqueous atmospheric corrosion of  $\sim 80\%$ .

The critical humidity for the onset of atmospheric corrosion varies considerably as a function of surface condition. Two factors are paramount in controlling this. Firstly, physical adsorption on porous surfaces

will occur below the expected bulk equilibrium value (i.e., the saturated vapor pressure) due to capillary condensation. This is of obvious relevance in the development of corrosion product (rust) layers, which will retain water in their pores well below the RH of condensation. Secondly, and importantly, liquid condensation will tend to occur at reduced RH where surface chemical contamination exists. This is because the activity of water at the saturated concentration of the solute, is lowered significantly, **Table 6**.

Thus, in the absence of other factors, a surface that is contaminated with sodium chloride will condense an aqueous phase at  $RH > 75\%$  while for seawater (containing magnesium and calcium cations) condensation of an aqueous phase might be expected at all  $RH > 33\%$ . In the presence of porous corrosion products, capillary condensation will lower these values further.

### 3.01.4.1.2 Air-borne pollutants

Historically, the combustion-derived air-borne sulfur dioxide and nitrogen oxides have been the most important pollutant species in the atmosphere. Other air-borne pollutants including hydrochloric acid vapor, ammonia, dust, soot and salt aerosol particles are also of importance. However, given extensive pollution controls that are now placed on industry and transportation, combustion-derived species have been greatly reduced. For example, current European Union legislation<sup>77</sup> sets down limits for  $\text{SO}_2$ ,  $\text{NO}_x$  and particulates of less than  $10 \mu\text{m}$  for implementation no later than 2010, **Table 7**. Annual global sulfur dioxide emissions are estimated to have peaked at the end of the 1970s (75 Mtonnes) and have since dropped  $\sim 20\%$ .<sup>78</sup> In Europe, emissions have dropped much further and by 2010 are expected to be less than half their peak value. The impact on ground level pollutant concentrations is clearly considerable with a consequent reduction in atmospheric corrosion rates.

The significance of the amount of sulfur dioxide available for reaction at the metal surface (its presentation rate), rather than the concentration in the atmosphere, has been demonstrated by studying the effects of atmospheric flow rate. Thus, an increase in steel corrosion with increase in atmospheric flow rate at a constant volume concentration of sulfur dioxide has been observed by Vannerberg<sup>79</sup> and Walton *et al.*<sup>80</sup> Notwithstanding these findings, the effect of sulfur dioxide on the corrosion of steel is clearly seen in **Figure 13**, which plots historic data from the Sheffield area of the UK. This illustrates a clear relationship between sulfur dioxide in the atmosphere and the corrosion of steel exposed to it; the atmospheric  $\text{SO}_2$  concentration accounting for  $\sim 50\%$  of the observed variation in corrosion rate.<sup>81</sup>

The corrosion of steel in the presence of  $\text{SO}_2$  has been studied as a function of RH by a number of

**Table 7** EU air-borne pollution limits for 2010

Species	Averaging period	Limit value
$\text{SO}_2$	1 h	$350 \mu\text{g m}^{-3}$
	24 h	$125 \mu\text{g m}^{-3}$
	365 days	$20 \mu\text{g m}^{-3}$
$\text{NO}_x$	1 h	$200 \mu\text{g m}^{-3}$
	24 h	$40 \mu\text{g m}^{-3}$
	365 days	$30 \mu\text{g m}^{-3}$
Particulates < $10 \mu\text{m}$	24 h	$50 \mu\text{g m}^{-3}$
	365 days	$20 \mu\text{g m}^{-3}$

**Figure 13** Relationship between sulfur dioxide ( $\text{mg of SO}_2 \text{ per m}^3$ ) and corrosion, after. Reproduced from Chandler, K. A.; Kilcullen, M. B. *Br. Corr. J.* **1968**, 3.

workers, the first being Vernon whose data are reproduced in [Figure 12](#). Sydberger and Vannerberg later repeated this work extending it to include corroded surfaces.<sup>82</sup> Using isotopic labeling, they confirmed that on uncontaminated, polished iron, in 0.1 ppm  $\text{SO}_2$  little or no  $\text{SO}_2$  was absorbed at RH below 80% and no corrosion was observed. On pre-corroded iron at RH greater than 80% and in 0.10 ppm  $\text{SO}_2$ , sulfur was absorbed quantitatively.

This explains the historic observation that rust films formed in industrial atmospheres contain considerable amounts (5% or more) of ferrous sulphate.<sup>83,84</sup> However, the formation of iron sulfate only accounts for a small percentage of the overall metal loss and this does not explain fully the effect of  $\text{SO}_2$  on iron corrosion.<sup>85,86</sup> For example, there is evidence that steel that has been allowed to corrode in an atmosphere containing sulfur dioxide, continues to corrode at a similar rate, at least for a time, after transferring it to a clean atmosphere.<sup>87</sup>

Historically, a cyclic variation in the amount of sulfate found in rust formed on steel exposed at different times of the year [Figure 14](#), has been observed. The quantity present depends on the month of the year rather than on the period of exposure, at least for periods of up to 2 years.<sup>88</sup> Consequently, the month of initial exposure will have an important influence on the corrosion rate. For example, in one test, specimens exposed for 2 months from September corroded at  $35 \mu\text{m year}^{-1}$  compared with  $136 \mu\text{m year}^{-1}$  for specimens exposed from May. This effect was of importance in planning for atmospheric exposure tests for steel since different annual corrosion rates would be obtained depending on whether the initial exposure was carried out in the summer or the winter months. The observed variation was historically

**Figure 14** Sulfate in adherent rust on steel exposed at Battersea in January after. Reproduced from Chandler, K. A.; Stanners, J. F. *Proceedings of 2nd International Congress of Metallic Corrosion*; NACE: Houston, 1963; 325.

related to the quantity of ground-level atmospheric  $\text{SO}_2$  present at different times of the year, which varied according to the burning of domestic coal for space and water heating. However, this source of  $\text{SO}_2$  is no longer present and it might be assumed that the observed difference is now considerably less.

Historically, sulfur dioxide was the most important gaseous pollutant present in the atmosphere. However, given the considerable reduction in ground level  $\text{SO}_2$  concentration over the last 30 years other species, particularly oxides of nitrogen ( $\text{NO}_x$ ), have increased in importance.<sup>89</sup> Nitrogen oxides are

produced during combustion as a consequence of direct reaction between nitrogen and oxygen in the air at high temperature. Increased thermal efficiency of plant, where the combustion temperature is raised, inevitably increases the production of  $\text{NO}_x$ . Thus, at elevated temperatures the following reactions occur:

The ratio of NO to  $\text{NO}_2$  is controlled by the reaction temperature and by the cooling time; faster cooling rates favoring  $\text{NO}_2$  over NO.

Several attempts have been made to study the influence of nitrogen oxides alone and in combination with sulfur dioxide, on the corrosion of steel, however no clear answer exists. In multiregression studies under atmospheric exposure in Japan no significant correlation with measured  $\text{NO}_x$  levels was found.<sup>90</sup> Likewise Haynie, in laboratory tests, found no correlation with  $\text{NO}_x$  levels and the corrosion or weathering steel.<sup>91</sup> Later work by Johansson clarified this situation. He found that, on its own, the increase in the atmospheric corrosion rate of steel, which was not large, was independent of RH.<sup>92</sup> However, a strong synergism was found with small levels of  $\text{NO}_x$  in combination with  $\text{SO}_2$ , which were much more corrosive than either pollutant on its own. This behavior is believed to be caused by the considerably more rapid solution-phase oxidation of sulfite to sulfate species in the presence of  $\text{NO}_x$  as oxidizer.<sup>93</sup>

One of the confusing aspects to the effect of  $\text{NO}_x$  pollutant is that it is a mixture of NO and  $\text{NO}_2$ . In order to separate the effects of these species on steel, Oesch carried out a series of laboratory experiments<sup>94</sup> in controlled pollutant gas mixtures. He found that NO had almost no effect on corrosion irrespective of RH, which is no doubt due to its low solubility in water. Conversely,  $\text{NO}_2$  caused a significant increase in corrosion rate although its effect was much lower than for  $\text{SO}_2$  (the corrosion rate in 10 ppm  $\text{NO}_2$  was about one-half that in 0.5 ppm  $\text{SO}_2$ ).

Hydrochloric acid gas is produced during the combustion of coals containing chloride species. Given its high solubility in water it might be expected also to influence corrosion although in rainwater its presence will only be evident from a higher chloride concentration than expected from sea salt and a lower pH. Askey *et al.* studied the effect of hydrochloric acid gas on corrosion of steel at varying atmospheric

presentation rates.<sup>95</sup> They found that the influence on corrosion of steel was high but reached a plateau where further increases in concentration did not increase the rate of corrosion. This was explained by the formation of iron chloride on the surface that oxidized to iron oxy-hydroxide liberating chloride. Thus, once sufficient chloride is present, further increases should have no additional effect.

Many other pollutant species are present in the atmosphere, including:  $\text{H}_2\text{S}$ ,  $\text{NH}_3$ , etc. Most of these arise from biological processes and are present at low concentration or have limited effects. Ammonia, the only significant basic atmospheric constituent, is produced via biological activity (e.g., primarily farming) and industrially. It has an extremely high solubility in water and consequently has a low residence time in the air. It is, however, a significant component of atmospheric aerosols typically forming ammonium sulfate or chloride.

#### 3.01.4.1.3 Particulates

Solid particles suspended in the atmosphere may also have influence on corrosion. They generally comprise three classes of material: dusts (e.g., from erosion of soil or sand), soots (i.e., derived from incomplete combustion) and aerosols (primarily sea salt and ammonium sulfate). Particles of all types play an important role in atmospheric corrosion as was found by Vernon and shown in Figure 12. They act as nuclei for the initial corrosion attack and as some particles are hygroscopic their presence tends to increase the periods of wetness of the steel surface. The most important particulate species in industrial atmospheres was historically ammonium sulfate, although chlorides<sup>96</sup> also have an effect. In marine environments (and as the ground-level  $\text{SO}_2$  concentrations decrease, increasingly in most environments) sea-derived chlorides have the most pronounced effect. In the presence of chlorides, rusting can continue at humidities as low as 35%.<sup>97,98</sup> As a rule, the chloride concentration in the air falls off rapidly with distance inland, but steel rusts at almost incredible rates on surf beaches where it is exposed to a continuous spray of sea salts. This is shown by the results of some tests made in Nigeria that are given in Table 8 and are confirmed in numerous other tests by other workers over many years. Cole and co-workers have developed a holistic model of atmospheric corrosion that considers the generation of salt in the ocean, its long-range transport and final deposition on materials as a function of distance from the sea.<sup>99,100</sup>

The number and composition of particulate matter in the atmosphere has changed markedly in view

of the change in overall pollution levels. Thirty years ago in the UK, the most aggressive species were: salt and salt/sand from marine or deiced locations, emitted ash from iron smelters, plume ash from incinerators and coal-fired boilers, and coal mine soot and dust.<sup>101</sup> However, the first of these sources now dominates the impact on corrosion. Detailed analysis of the nature and form of particulates is possible provided care is taken to separate and secure the water-soluble aerosol component. A recent analysis of air-borne solids in Hong Kong<sup>102</sup> has identified, for that location, three principle sources of ions derived from atmospheric particulates: fine aerosols derived from atmospheric transformations (e.g., the reaction of sulfate with ammonia to produce ammonium sulfate); coarse particles derived from soils and sea salt derived aerosol, **Table 9**.

Particles were found to have a bimodal size distribution with the larger particles in the size range 2–10 µm and the smaller particles in the range 0.1–1 µm. The effect on corrosion was found to depend on the size of the aerosols, which was also related to their composition. Thus, rusts formed from the finer aerosol particles have composition related to sulfates, while those from coarse particles are mainly related to

chloride. Sea salt was found to contribute most to the corrosion of mild steel while calcium ions inhibited corrosion. Ammonium, potassium, and magnesium ions had much less of an effect on the corrosion of steel.

The effect on corrosion of combustion derived ashes (fly-ash) from coal and oil, as well as inert glass powder of similar size range as studied by Askey *et al.*<sup>103</sup> They found that the ashes from oil combustion were considerably more corrosive than those derived from coal combustion due to the much higher acidity of the former. In general, the effect of the fly-ash particulates was in approximate proportion to the quantity of ions that were released into solution indicating that a primary mechanism controlling corrosion was the resistance of the surface electrolyte. The presence of inert borosilicate glass particles on the steel surface was found to have a small, but statistically significant affect on the corrosion rate, increasing it by between 50% and 100% compared with the clean, uncontaminated surface. This effect was ascribed to a mechanism involving local differential aeration at the microcrevice formed between the particle and the surface.

### 3.01.4.2 Mechanism of Atmospheric Corrosion of Iron

#### 3.01.4.2.1 Acid regeneration cycle

Atmospheric corrosion of steel tends to initiate at local sites on the metal surface. The initial distribution of corroding sites is correlated with the presence of active surface-breaking manganese sulfide inclusions. These dissolve to form sulfide species that react locally with iron forming sulfide films that promote local corrosion.<sup>104,105</sup> As noted previously, sulfur dioxide from the air also absorbs onto the surface of clean steel, and into rust layers, and reacts to form a sulfate-containing electrolyte in the rust. During corrosion, ferrous sulfate is formed, which then reacts with atmospheric oxygen to form iron oxy-hydroxide:

In this way, the sulfate is regenerated and the local acidity is increased. Nests of sulfate species are frequently found in corrosion products after atmospheric exposure and the mechanism is consistent with these observations. Recent work using high-resolution analytical studies have found that the initial absorption of sulfur dioxide, and subsequent corrosion of steel, was local in nature. Importantly, it was found that SO<sub>2</sub> on its own is insufficient to

**Table 8** Effect of sea salts on the rate of corrosion of ingot iron<sup>a</sup>

form sulfate nests and the presence of an additional oxidant ( $\text{NO}_2$  or  $\text{O}_3$ ) was essential for the detection of sulfate nests.<sup>106</sup>

### 3.01.4.2.2 The electrochemical mechanism

An electrochemical mechanism for atmospheric rusting was first proposed by Evans in 1963, but was not accepted at the time.<sup>107</sup> Its basic conception is that an electrochemical cell is formed between iron and iron oxy-hydroxide. At the anode, ferrous ions are produced in the normal way while at the cathode  $\text{FeO}(\text{OH})$  is reduced. At some later point, the reduced iron oxide is reoxidized by atmospheric oxygen<sup>108</sup>; hence, a net increase in the amount of  $\text{FeO}(\text{OH})$  ensues. Evans' original cycle is reproduced below:

The above mechanism is now generally accepted although the indicated role of magnetite as the reduced species is probably only true under relatively reducing conditions. Thus, electrochemical reduction of lepidocrocite,  $\gamma\text{-FeO}(\text{OH})$ , results in a thin surface layer containing  $\text{Fe}^{2+}$  species which may either dissolve into the electrolyte or, at more negative potentials, may form magnetite.<sup>109</sup> The reduced surface layer, containing ferrous hydroxide, is easily reoxidized back to  $\gamma\text{-FeO}(\text{OH})$ . Hence, reactions [29] and [30] become:

On the other hand, magnetite oxidizes preferentially to maghemite,  $\gamma\text{-Fe}_2\text{O}_3$ , which is relatively resistant to reduction, as is magnetite. Likewise, goethite,  $\alpha\text{-FeO}(\text{OH})$ , is considerably more resistant to electrochemical reduction compared with lepidocrocite.<sup>110</sup> Hence, the electrochemical mechanism will only operate where there is sufficient lepidocrocite present while rusts largely containing goethite would be expected to be resistant to reduction and, hence, dimensionally more stable and more protective.

### 3.01.4.2.3 The wet-dry cycle

During atmospheric exposure of any material, a repeated, endless, and chaotic cycle of wetting and drying occurs, caused by precipitation, heat and wind drying of wetted surfaces, absorption and deposition of pollutants and wetting and drying of surfaces as a function of the RH. The cycles of wetting and drying strongly influence the corrosion of materials. For steel that this cycle is an essential part of the electrochemical mechanism described above was confirmed by an elegant series of experiments by Stratmann and co-workers.<sup>111–114</sup> In these studies, the mass loss of iron and the oxygen consumption rate were measured simultaneously as a function of the wetting and drying of the iron surface. The outstanding feature of the variation in corrosion rate with wetting and drying cycle, **Figure 15**, is the surprisingly large contribution that occurs during the drying part of the cycle. This was the first experimental evidence to demonstrate this unexpectedly large effect, which has since been confirmed for other materials during atmospheric corrosion.<sup>115</sup>

Notable from **Figure 15** is the profound effect on the corrosion rate during drying that is a result of the alloying copper with iron. This work thus provides insight into the well-known beneficial effect of copper on the atmospheric corrosion of low alloys steels. This is discussed in more detail below.

### 3.01.4.3 Corrosion Product Composition

Until quite recently, it was not thought useful to analyze rusts in detail partly because X-ray diffraction indicated that they were poorly crystalline. Notwithstanding this, it was known that corrosion products on steel during atmospheric exposure were similar to those formed in immersed conditions as might be expected by consideration of the electrochemical mechanism of corrosion. Thus, corrosion products on plain carbon steel after atmospheric rusting contain magnetite,  $\text{Fe}_3\text{O}_4$ , lepidocrocite,  $\gamma\text{-FeO}(\text{OH})$  and goethite,  $\alpha\text{-FeO}(\text{OH})$  in varying amounts, the last being thermodynamically the most stable.

Recently, rather detailed studies have begun to be performed using a variety of techniques. A Mössbauer analysis of the corrosion products on mild steel after 35 years exposure in a semirural Japanese location found that the rusts were composed mostly of goethite with minor amounts of lepidocrocite and trace amounts of magnetite.<sup>116</sup> In addition, the crystallite size of the goethite component was found to be

**Figure 15** Atmospheric corrosion rate of Fe and Fe-0.5%Cu alloy over the 4th cycle of wetting ( $20^\circ\text{C}$ ) and drying ( $40^\circ\text{C}$ ), after. Reproduced from Stratmann, M.; Bohnenkamp, K.; Ramchandran, T. *Corros. Sci.* **1987**, 27(9), 905–926.

bimodal, with more than 80% larger than 12 nm but the remaining fraction smaller than 9 nm. In laboratory experiments, the composition of adherent and nonadherent rusts formed by artificially corroded steel at varying chloride concentrations were also studied by Mössbauer analysis. Nonadherent rust was found to consist of lepidocrocite, goethite, with traces of akaganeite and magnetite.<sup>117</sup> The composition of the corrosion products was essentially independent of the exposure times and chloride concentration. Studies of steels exposed over 16 years in various industrial locations in the United States found similar compounds with the difference that maghemite was identified rather than the isostructural magnetite.<sup>118</sup>

In summary, the corrosion product (rust) layer that is developed on steel after long-term exposure in the atmosphere contains species that may be expected from thermodynamic considerations. Thus, the majority component is the most stable phase (goethite), which appears as the outer, and thickest, layer. Depending on the environment and conditions of exposure, an intermediate layer of corrosion product contains lepidocrocite while magnetite and maghemite are concentrated in a region adjacent to the steel substrate, although they may also be present as isolated crystallites within the intermediate layer. In marine environments, minor amounts of akaganeite are also commonly present. The phases are all finely grained (and commonly nano-crystalline) with a decrease in grain size and an increase in the volume fraction of goethite associated with improved corrosion resistance.

### 3.01.4.4 Atmospheric Corrosion Kinetics

#### 3.01.4.4.1 Climatic variation

Some representative figures to show how the rate of corrosion of carbon steel in the open air varies in different parts of the world are given in Table 10. They relate to  $100 \times 50 \times 3.2$  mm pieces of ingot iron freely exposed in a vertical position for 1 year and derive from historic data from the former BISRA.<sup>8</sup>

The results follow an expected pattern with by far the highest rate of corrosion being observed on a surf beach at Lagos, Nigeria. Indeed, this environment is so aggressive that the measured corrosion rate is several times that expected under immersed conditions. Conversely, the low rates of corrosion observed at Khartoum, Abisko, Delhi, Basrah, and Singapore are primarily associated with the absence of serious pollution. Moreover, at most of these locations the RH is low, for example, at Khartoum the RH lies below the critical value for rusting throughout the whole year.

Despite these results, it should not be assumed that corrosion rates of steel will necessarily be low in all comparatively nonpolluted desert environments. In regions such as the Arabian Gulf, considerable variations in corrosion rates may occur between inland and coastal sites. This arises not only from the salt content of the air but also from sand which is blown on to the steel. Although temperatures are high during the day, condensation occurs at night. The effects of different types of sand on the corrosion of mild steel have been studied.<sup>119</sup> It was concluded

**Table 10** Atmospheric corrosion rates of mild steel exposed outdoors in different climates

that fine sand has a higher salt content and is more corrosive than coarse sand within the size range  $<0.25\text{--}2.4\text{ mm}$ . Similarly in Canadian arctic and sub-arctic conditions corrosion rates as low as  $2\text{--}5\text{ }\mu\text{m year}^{-1}$  were recorded at inland sites while within 1 km of the sea much higher rates ( $21\text{--}34\text{ }\mu\text{m year}^{-1}$ ) were measured.<sup>120</sup> Thus, the rate of atmospheric corrosion is, as expected, dependent upon the local pollutant concentrations (e.g., affecting the surface chemistry and electrochemistry) as well as the local climatic conditions (e.g., controlling the total duration of corrosion, or time of wetness). It is important to remember that all quoted corrosion rates relate to average general penetration and take no account of pitting. Serious pitting of steel exposed to atmospheric corrosion is uncommon on simple test plates. However, it may be necessary to allow for this in some practical cases, where local attack may be occasioned by faulty design and other factors.

In reviewing this data, despite its historic nature, there is no reason to doubt the validity of the results in similar conditions. Thus, rates for the

atmospheric corrosion of steel can be expected to vary from exceptionally high  $>600\text{ }\mu\text{m year}^{-1}$ , to very low  $<5\text{ }\mu\text{m year}^{-1}$ . What has changed, and this is an important consideration, is that the industrial pollutant concentrations have decreased dramatically over the last 20–40 years and that rate data for a particular location (especially if it is inland and was close to industry) may no longer be valid.

#### 3.01.4.4.2 Conditions of exposure

It has long been known that sheltering and orientation of exposed steel during atmospheric corrosion testing influences significantly the measured corrosion rates. For example, the results of tests at Derby in the 1940s<sup>121</sup> show that specimens exposed at  $45^\circ$  to the horizontal corroded 10–20% more than specimens exposed vertically and that 54% of the total loss was on the underside. Likewise, for similar American tests<sup>122</sup> on specimens exposed at  $30^\circ$  to the horizontal, 62% of the total corrosion loss was on the underside. This influence is further demonstrated in experiments carried out 228 m from the sea at Kure Beach, North Carolina.<sup>123</sup> In these tests, the corrosion rates over a 4-year period varied by a factor of five depending on the orientation and degree of sheltering. Generally, east (sea) facing specimens exposed at  $30^\circ$  from the horizontal corroded at the highest rate while west (land) facing specimens exposed at the same angle corroded at the lowest rate. This can be ascribed to the prevailing wind direction driving sea salt aerosols onto the specimens.

The orientation of steel during atmospheric exposure tests is therefore found to have great influence on the final corrosion rates measured. This is because the amount of moisture and pollutants that can reach, and remain on, surfaces vary with compass direction, prevailing wind, sun, etc. In particular, the ground-facing side of a horizontal surface is protected from rain but it is also shielded from the drying action of the sun and often of the wind. Thus, condensation tends to remain in contact with the steel there for longer periods; moreover, harmful solid particles and soluble salts are not washed away by rain events. Consequently, and possibly counter intuitively, the ground-facing side is often found to corrode more rapidly than the sky-facing side. The same considerations apply to steel exposed obliquely. The relative corrosion of the opposite faces of a vertical steel plate will largely depend on the direction of the prevailing winds, pollution, rain and sun (i.e., whether the face is oriented towards the south (in the north of the equator) or the north (in the south of the equator).

### 3.01.4.4.3 Damage functions

Generally, in the majority of environments, except those that have exceptionally high levels of pollutant or salt aerosol, the corrosion rate of steel tends to decrease with time. This is a common observation, for example in recent work by Zhang *et al.*<sup>124</sup> for two different types of steel in a marine environment, **Figure 16**.

As may be seen in **Figure 16**, the tendency is for corrosion rates to decrease with time. Such behavior may be modeled simplistically by an exponential expression such as:

$$\text{Rate} = A t^n \quad [33]$$

where  $A$  is a constant,  $t$  is time and  $n$  is the kinetic rate order (or exponent). For  $n$  equal to 1, linear kinetics ensue and the reaction rate is likely to be chemical reaction controlled however, for diffusion-controlled parabolic kinetics,  $n$  is equal to 0.5. Any other value for  $n$  implies a mixed control process. For atmospheric corrosion of steel, the value of  $n$  commonly lies between 0.5 (more typical of weathering steel) and 0.8 (more common for carbon steel).

Traditionally field exposures have been used to determine the corrosion rates of materials at particular environments. Initially, just corrosion rate data were collected but gradually such work was extended to include simultaneous collection of an increasing range of other atmospheric data, including: RH, air and metal temperature, precipitation, sunlight, as well as deposition of chloride, sulfate, nitrate, and analysis of rain water. The concept behind this considerable amount of effort is to develop damage functions (or dose–response relationships) for atmospheric corrosion

so that predictive models may be developed. This approach culminated with an international program run under the auspices of the International Standards Organisation Technical Committee 156, Working Group 4 (ISO TC156/WG4) and the collaboration of 12 nations (Canada, Czechoslovakia, Finland, France, Germany, Japan, Norway, Spain, Sweden, UK, USA, and Russia) that commenced in 1986. The primary purpose of this was to verify the ISO 9223–9225 classification standards for the aggressiveness of atmospheres. A secondary, arguably more scientific, purpose was to collate the results across numerous and widely geographically separated locations in order to determine the best fit to the data by multivariate least squares regression analysis.

Results from the ISO-CORRAG program were published gradually over a number of years for example by Dean *et al.*<sup>125–127</sup> Generally, the data show strong correlation between the corrosion rates for steel with the corrosion rates of the other tested materials (zinc, copper, aluminum) as might be expected. However, the scientific aim, which was to describe the corrosion rate of materials effectively as a regression equation over the main variables, was not completely successful. Thus, the use of the exponential rate expression alone was found to account for ~75% of the observed corrosion rate variation for steel. Regression of the time exponent against time of wetness and chloride deposition rate improved the regression fit only slightly. A more complete analysis of the data by Mikhailov, Tidblad, and Kucera<sup>128</sup> resulted in two rate expressions that reflect the observed increase in corrosion rate with temperature to 10 °C, thereafter decreasing:

Below 10 °C:

$$C = 1.77[\text{SO}_2]^{0.52} \exp(0.020RH) \exp\{0.150(T - 10)\} \\ + 0.102[\text{Cl}^-]^{0.62} \exp(0.033RH + 0.040T)$$

Above 10 °C:

$$C = 1.77[\text{SO}_2]^{0.52} \exp(0.020RH) \exp\{-0.054 \\ (T - 10)\} + 0.102[\text{Cl}^-]^{0.62} \\ \exp(0.033RH + 0.040T)$$

where:  $C$  is the corrosion rate of steel ( $\mu\text{m year}^{-1}$ ),  $RH$  is relative humidity (%),  $T$  is temperature (°C),  $[\text{SO}_2]$  is the concentration of sulfur dioxide ( $\mu\text{g m}^{-3}$ ) and  $[\text{Cl}^-]$  is the chloride deposition rate ( $\text{mg m}^{-2} \text{day}^{-1}$ ). These expressions, regressed over 128 datasets, provide a correlation coefficient ( $R^2$ ) of 0.85. Dean commented on the overall results of the ISO-CORRAG program:

**Figure 16** Thickness loss of weathering steel and mild steel versus exposure time. Reproduced from Zhang, Q. C.; Wua, J. S.; Wang, J. J.; Zheng, W. L.; Chen, J. G.; Li, A. B. *Mater. Chem. Phys.* **2003**, 77(2), 603–608.

“Some other environmental variables will need to be found to improve this approach to predicting atmospheric corrosion.” Nevertheless, the fact that comparatively simple rate expressions may be used to provide a guide to atmospheric corrosion prediction is helpful.

Kinetic rate parameters can be measured with more control in the laboratory. For example, activation energies and reaction rate orders as a function of chloride contamination and gas-phase  $\text{SO}_2$  concentration have been determined in the laboratory for the early stages of the atmospheric corrosion of iron (i.e., between 0 and 120 h).<sup>129</sup> From the data in [Table 11](#) it can be noted that for exposure in gas-phase  $\text{SO}_2$ , activation energies, and kinetic and chemical rate orders, are consistent with the controlling mechanism for atmospheric corrosion of iron being slow solution-phase oxidation of sulfite to sulfate ion. Conversely, the corrosion process with surface chloride contamination is evidently much easier. These data provide input into corrosion models that may be extended out to longer exposure times in order to generate predictive corrosion models.

### 3.01.4.5 Weathering Steel

#### 3.01.4.5.1 Alloying effects

Historically, from the 1940s, a large degree of effort was put into the development of low alloy steels that had improved overall corrosion resistance. By the early 1960s and into the 1970s, this program of testing had largely been completed with the development of a generation of optimized weathering steels based on steel compositions containing at least 0.2% Cu with small additional amounts of P and Cr. The beneficial effect of copper additions to steel has been referred to already in [Figure 15](#) and [Figure 16](#). In turn, [Figure 17](#) refers to trials of 9 years duration at Rotherham in the

United Kingdom<sup>130</sup> while similar curves based on American tests,<sup>131</sup> in [Figure 18](#), show substantially the same features. The fact that the rates of corrosion are markedly slower in the American than in the British tests is mainly due to differences in the corrosiveness of the respective atmospheres.

The effects of the various alloying elements are not necessarily directly additive although same additions are synergistic (e.g., Cu+P is better than Cu on its own). Bearing this in mind, the practical effect of individual elements can be summarized as follows.

- Copper additions up to ~0.4% give a marked improvement, but further additions make little difference.
- Phosphorus, at least when combined with copper, is also highly beneficial. However, in practice, levels above ~0.10% adversely affect mechanical properties.
- Chromium, in fractional percentages, has a significant influence on corrosion rates.
- Nickel, while reducing corrosion rates a little, is not as important in its effect as the aforementioned elements.
- Manganese may have a particular value in chloride-contaminated environments, but its contribution is little understood.
- Silicon is in a similar position to manganese, with conflicting evidence as to its value.

#### 3.01.4.5.2 Wetting and drying

The improvement in corrosion resistance for weathering steels compared with carbon steel is found to depend on the nature and amounts of the alloying elements and the corrosive environment. Thus, weathering steels show greatest advantage when they are freely exposed to the open air in industrial environments, that is, where they are subjected to atmospheric

wetting and drying. The effect of variations in surface wetting is illustrated in **Figure 19**, which compares the relative rates of corrosion of a weathering steel and a carbon steel at a UK industrial location after 9 years exposure.<sup>132</sup> The greatest rate of corrosion was on panels facing the north-westerly direction, which is wettest for the longest period of time.

Initially, weathering steel appears to corrode like mild steel. However, unlike mild steel whose oxide repeatedly spalls off, the surface rust layer on weathering steel stabilizes with time, provided that the exposure conditions allow the steel to dry out periodically. The rust then becomes darker, granular, and tightly adherent whilst any pores or cracks

become filled. This protects the underlying steel by reducing the permeability of the oxide layer to water and air both of which must be present simultaneously at the metal surface for rusting to continue.

The distinguishing feature of the behavior of the slow-rusting low-alloy steels is the formation of this protective rust layer, which generally contains a finer grained (nano-crystalline) oxide particles and a higher proportion of the stable goethite phase compared with the rust layers formed on carbon steel. The first mechanistic evidence for this improvement in performance was made by Stratmann and is shown in **Figure 15**. In copper-free steel, a large fraction of the total corrosion process occurs during the drying phase of the wet-dry cycle. However, for copper-containing steel, the large increase in corrosion rate towards the end of the drying cycle is absent.<sup>112</sup> The precise reason for this suppression is not yet wholly clear however, it may be interpreted in terms either of a stabilization of iron oxy-hydroxide (rust) to reduction or in terms of the cathodic reduction of oxygen being inhibited.<sup>133</sup> Either way, the redox cycling (and associated volume changes) is suppressed resulting in a more compact and more protective rust layer.

### 3.01.4.5.3 Applications

The most widespread use of weathering steels has been for structural steelwork in buildings, bridges, roadside furniture, etc. especially where maintenance painting is particularly difficult, dangerous, inconvenient, or expensive. Bridges over land, rivers, railways, roads and estuaries fall into this category, although in the last two cases care should be taken with respect to airborne salinity and ensuring adequate drainage to

**Figure 17** Effect of low-alloy additions on the corrosion of steel in Rotherham, UK. Reproduced from Edwards, A. M. *Proc. Symp. on Developments in Methods of Prevention and Control of Corrosion in Buildings*, British Iron and Steel Federation, London, 1966.

**Figure 18** Effect of low-alloy additions on the corrosion of steel outdoors at Kearny, NJ, USA. Reproduced from Larrabee, C. P.; Coburn, S. K. *Proc. First International Congress on Metallic Corrosion*, 1962; Butterworths: London, pp 276.

avoid the possibility of continuous wetting. Road bridges can be affected by salt-laden atmospheres or water, produced as a consequence of winter ice and snow clearing with deicing salt and grit. Chloride can be in the form of an airborne spray thrown up by passing vehicles or as a result of leaks in the bridge deck. In the presence of salt-water many materials, including steel, paint, reinforced concrete, aluminum, etc. deteriorate at an accelerated rate. Weathering steels are no exception, and higher than normal corrosion rates should be expected if they are exposed to saline waters or frequent spraying with salt. Albrecht has described the applications and pitfalls of using weathering steel in US highway bridges in an informative paper that is well worth consultation.<sup>134</sup>

#### 3.01.4.5.4 Next generation weathering steels

Recent research has been aimed at further optimization of the performance of weathering steels, partly by more detailed understanding of the nature of the rusts that are formed during exposures. Thus, X-ray diffraction, vibrational spectroscopy, and elemental analysis have all been applied to the analysis of various rusts on the micrometer scale. This has provided evidence of doping of the rust layers by  $\text{Cr}^{3+}$  and

$\text{Ni}^{2+}$ , which, in turn, limits cathodic oxygen reduction and promotes the stabilization of the goethite phase.<sup>135,136</sup> In the light of these results, more advanced weathering steels, based on modern high-strength, low-alloy compositions, have been developed,<sup>137</sup> Table 12.

The substitution of nickel for chromium, and the slightly increased level of copper, results in a considerably improved performance particularly in those atmospheres where the importance of chloride has increased due to the reduction in sulfur dioxide levels. The amount of corrosion on the novel material was less than 1/20 that of conventional weathering steel after 9 year exposure to a marine atmosphere in Japan.<sup>136</sup> It was suggested that this improved performance was due to nickel doping of the rust that resulted in an ion exchange process leaving a net negative charge at the inner rust layer, hence 'repelling' chloride ions.

#### 3.01.4.6 Classification of Atmospheres

Classification of the atmosphere into various corrosivity (i.e., severity of corrosion) categories depending on local environment has been the work of a

**Figure 19** Corrosion losses of steels exposed vertically, facing different compass directions. Reproduced from Hooper, R. A. E.; Lee, B. V. Proc. 12th International COR-TEN Conference, Florida, 1985, United States Steel, Pittsburgh, 1985.

number of national standards bodies. In the EU, this standardization is encompassed within BS EN 12500,<sup>138</sup> and consistent with ISO 9223–9226. The standard atmospheric corrosivity classifications are reproduced in **Table 13** with the corresponding expected corrosion rates for carbon steel in **Table 14**.

An example of this approach is given in **Table 15** where corrosion rates in various European (mainly Scandinavian) locations are matched to **Table 14** to derive an atmospheric corrosivity classification for that location.

### 3.01.5 Corrosion in Water

#### 3.01.5.1 Water Composition

The composition of water is clearly of importance in determining the rate of corrosion of steel exposed to it. Some of the more important factors that contribute to corrosion are the dissolved gas content (primarily

oxygen and carbon dioxide), the nature and amount of dissolved solids (which influences the electrical conductivity, pH and hardness of the water), the presence of organic matter (such as detergents, oils, wastes, etc.) and the presence or absence of microbial species such as bacteria, algae, or fungi.

##### 3.01.5.1.1 Dissolved gases

Oxygen is the most important dissolved gas in water and, at  $\text{pH} > 3$ , is generally the main cathodic reactant for the corrosion of steel. Thus, in neutral or near-neutral water, dissolved oxygen is necessary for any appreciable corrosion of steel. Increasing the oxygen availability for reaction either by increasing the dissolved oxygen concentration or by increasing its mass transfer rate (i.e., in a flowing system) will, in almost every case, result in an increase in corrosion rate. In view of this, the control of oxygen concentration in solution is one of the primary methods for

**Table 13** ISO standard classifications for atmospheric corrosivity

Corrosivity category	Corrosivity	Examples of typical environments	
		Indoor	Outdoor
C1	Very low	Heated spaces with low RH and insignificant pollution: schools, museums, etc.	Dry or cold zonesatmospheric environment with very low pollution and time of wetness for example, certain deserts, central Antarctica
C2	Low	Unheated spaces with varying temperature and RH. Low frequency of condensation and low pollution, for example, storage, rooms, sports halls	Temperate zones: environment with low pollution ( $\text{SO}_2 < 12 \text{ mg m}^{-3}$ ), for example, rural areas, small towns. Dry or cold zones: environment with short time of wetness, for example, deserts, subarctic areas
C3	Medium	Spaces with moderate frequency of condensation and moderate pollution from production process, for example, food-processing plants, laundries, breweries, dairies	Temperate zone: environment with medium pollution ( $\text{SO}_2: 12\text{--}40 \text{ mg m}^{-3}$ ) or some effect of chlorides, for example, urban areas, coastal areas with low deposition of chlorides
C4	High	Spaces with high frequency of condensation and high pollution from production process, for example, industrial processing plants, swimming pools	Tropical zone: atmosphere with low pollution Temperate zone: environment with high pollution, ( $\text{SO}_2: 40\text{--}80 \text{ mg m}^{-3}$ ) or substantial effect of chlorides, for example, polluted urban areas, industrial areas, coastal areas, without spray of salt water, strong effect of deicing salts. Tropical zone: environment with medium pollution
C5	Very high	Spaces with almost permanent condensation and/or with high pollution from production process, for example, mines, caverns for industrial purposes, unventilated sheds in humid tropical zones	Temperate zone: environment with very high pollution ( $\text{SO}_2: 80\text{--}250 \text{ mg m}^{-3}$ ) and/or strong effect of chlorides, for example, industrial areas, coastal and off shore areas, with salt spray. Tropical zone: environment with high pollution and/or strong effect of chlorides

Source: BS EN 12500: Protection of metallic materials against corrosion: Corrosion likelihood in atmospheric environment, classification, determination and estimation of corrosivity of atmospheric environments.

corrosion control of carbon steel (and indeed many other materials).

The presence of dissolved ambient carbon dioxide from the atmosphere ( $p\text{CO}_2 \sim 385$  ppm in 2008) alters the pH of water by the reaction:

Indeed, the pH of most natural (nonsaline) water exposed to the atmosphere is acidic due to the above equilibrium. Thus, changes in the dissolved  $\text{CO}_2$  level will tend to change the pH and, consequently, any process that depends upon pH. In near-neutral solutions, this will not affect the corrosion rate of steel directly. However, a change in pH may affect the stability of protective deposits and scales on the steel, particularly those containing calcium carbonate, which will tend to dissolve as the pH falls.

At higher  $\text{CO}_2$  pressures the situation changes significantly. Thus, in 3% sodium chloride solution at 1 atm. of carbon dioxide the corrosion rate of steel is increased substantially above what might be expected at the equilibrium pH of  $\sim 3$  with hydrogen

evolution as the cathodic reaction. Although the concentration of hydrogen ions in solution is relatively low at pH 3 (i.e.,  $10^{-3}$ ), carbonic acid dissociates as shown in eqn [34] to produce hydrogen ions immediately adjacent to the cathode. Thus, under these conditions, the hydrogen evolution reaction is controlled by mass transfer of carbonic acid to the cathode.<sup>139</sup>

This mechanism largely explains the phenomenon of 'sweet' corrosion, due to  $\text{CO}_2$  in oil and gas recovery and petrochemical production.

### 3.01.5.1.2 Dissolved solids

The effect of dissolved solids is complex. The presence of inorganic salts, notably of chlorides and sulfates, should promote corrosion, because they increase the conductivity of the water, thereby facilitating the electrochemical reactions via improved ion transport in solution. Alkaline waters tend to be less aggressive than acid or near-neutral waters, and corrosion can be well-controlled in a closed system by appropriate water treatment; for example, addition of inhibitors and/or making the water alkaline and the metal passive. Unfortunately, at pH values just insufficient to give complete passivation, there is a high risk of severe pitting, even though the total corrosion rate is reduced, and this is a greater danger in many applications.

The most important property of dissolved solids in fresh waters is whether or not they lead to deposition of a protective film on the steel that will impede the corrosion process. This is determined mainly by the equilibrium between calcium carbonate, calcium bicarbonate, and carbon dioxide and is of fundamental significance and where an appropriate scaling index (e.g., the Langelier index) can provide guidance.<sup>140</sup> Since hard waters are more likely to deposit a protective calcareous scale than soft waters, the former tend to be considerably less aggressive than the latter; also, soft waters can often be rendered less

**Table 14** Correspondence between mass loss of carbon steel after 1 year of exposure and ISO standard atmospheric corrosivity classifications

Corrosivity category	Mass loss per unit area ( $\text{g m}^{-2}$ )	Thickness loss ( $\mu\text{m}$ )

corrosive by treating them with lime (calcium hydroxide). Carbonate scales are not the only type that may form in water and, depending on water chemistry, scales of calcium sulfate, magnesium silicate, magnesium hydroxide and iron or manganese oxy-hydroxides may also form.

### **3.01.5.1.3 Microbial effects**

Another important factor is that most natural waters are far from being sterile. They contain greater or lesser amounts of organic matter, both living and dead. Some of the dead organic matter, for example, peat residues, may render the water corrosive by making it acid, but in most cases, the living organisms probably exert the greater influence. In natural seawater, fouling occurs and in freshwaters, algae may grow. A more detailed discussion of microbial corrosion can be found elsewhere in this book.

## **3.01.5.2 Deposits and Scales**

### **3.01.5.2.1 Fouling of surfaces**

During service, the surface of steel in contact with the environment will inevitably tend to become covered with a deposit of some nature. Such deposits may arise from the water chemistry (i.e., carbonate scaling), from corrosion (i.e., the formation of a corrosion product), from bio-films (i.e., slimes from bacterial, algal and other origins), from sediments and silts (i.e., from suspended solids in the water), etc. In all cases, the fouling of surfaces will have an effect on corrosion rates of materials used and on the process or function of the system. These effects need to be understood and allowed for in the design of the system. However, if the anticipated effects are detrimental, the surface fouling must be controlled in some way depending on its origin.

In many systems or processes, fouling deposits tend to form preferentially in the hottest part of the system, often on heat transfer surfaces (e.g., boilers, heat exchangers, etc.), because the solubility of the depositing material is lowered; this is particularly prevalent for carbonate scaling. In other cases, deposits tend to form at the coolest part of the system (i.e., also in heat exchangers) for the same reason. The formation of bio-films is clearly not an issue where the system temperature is sufficient to ensure sterilization. Conversely, in chilled water and air conditioning systems, bio-film formation is a significant hazard.

In addition to a reduction in the efficiency of heat transfer due to the isolation of the metal surface from

the water by a film of low thermal conductivity, fouling deposits can additionally cause significant problems due to constriction of flow, blocking of valves, etc.

### **3.01.5.2.2 Under-deposit corrosion**

Fouling deposits, depending on their nature, often result in enhanced corrosion underneath the deposit. On heat transfer surfaces at sufficiently high temperature, local boiling of water can occur beneath deposits giving rise to concentration of the species in solution at this point and consequent localized corrosion under the deposit. In the absence of heat transfer, under-deposit corrosion may still occur due to the differential aeration mechanism where the anode is localized to an area of lower oxygen concentration under the deposit.

Where water treatment is used to provide corrosion control, then the presence of deposits in the system will result in poor availability of the inhibitor at these locations and, again, increased corrosion will result. This is particularly significant where passivating inhibitors are used as the inhibitor concentration may locally (i.e., under the deposit) fall below the critical concentration required for passivity and, hence, give rise to a significant risk of pitting corrosion.

In many systems, a bio-film of an aerobic species may first colonize the steel surface, which will result in local oxygen depletion under the bio-film. The effect of this is both to promote differential aeration cell corrosion but, more significantly, to create a beneficial environment for possible further colonization under the original film by an anaerobic species, including sulfate reducing bacteria. In this latter case, the metabolic products include reduced sulfur species, particularly sulfides and hydrogen sulfide, both of which are very likely to promote severe corrosion.

## **3.01.5.3 Natural Waters**

### **3.01.5.3.1 Corrosion rates**

As pointed out already, corrosion rates of carbon steel in water vary significantly depending, amongst other things, upon the specific water composition, oxygen concentration, and flow rate in the fluid (i.e., the mass transfer rate of oxygen to the corroding surface). In practice, some form of corrosion protection is generally used for carbon steel in aqueous environments. In a few situations however, unprotected bare steel may be used provided a corrosion allowance is provided for in the design. Such applications include: pipe internals on potable water systems and fire protection systems, where only minimal (or no) water treatment

**Table 16** Rates of corrosion of mild steel in natural waters (total immersion)

Type of water	Test authority	Test site	Test duration	Average corrosion rate ( $\mu\text{m year}^{-1}$ )
Sea water	Institution of Civil Engineers <sup>141</sup> BISRA <sup>142</sup>	Halifax, Nova Scotia	15	108
		Plymouth	15	65
		Emsworth	5	65
Fresh water	Institution of Civil Engineers <sup>141</sup>	Plymouth: reservoir water	15	43
River water	Office Technique pour l'Utilisation de l'Acier <sup>143</sup>	La Cadène: soft water	5	68
		Dôle: hard water	5	10

is possible, etc.; and steel piles for shoring work (e.g., on river banks, jetties, etc.).

For interest, some historic data for corrosion rates in a range of environments are given in Table 16; for low-carbon structural steel tested under the conditions stated. The figures are for the average general penetration over the whole test areas. As an indication of the maximum penetration depth, it may be noted that in the sea-water tests of the Institution of Civil Engineers<sup>141</sup> the maximum depth of pitting for descaled mild steel after 15 years immersion was  $\sim 2.3$  mm; when the steel had been immersed in the as-rolled condition with its millscale, a Figure as high as 7.6 mm was observed. Under half tide immersion conditions, the corrosion rate of steel may be increased by a factor of 2–5 compared with the results for total immersion.

The rates of corrosion quoted in Table 16 are sufficiently low that with a suitable corrosion allowance they can be used unprotected with an anticipated life for structures of 40–50 years. Traditionally, low-strength steel grades were used for pipes and structural elements (such as piling) and required a relatively thick section for strength. Increasingly, such steels are being replaced with higher strength materials of thinner section resulting, obviously, in a decreased lifetime. It is not clear that design engineers fully appreciate that the good lifetime previously achieved for steel in waters was often due to generous thickness allowances with respect to strength and corrosion.

### 3.01.5.3.2 Piped fresh water systems

It is not uncommon for unprotected ferrous materials (i.e., cast iron or carbon steel) to be used in potable (drinking) water systems (as pipes, pumps, valves, etc.), in fire protection systems, as foundation or shoring materials (i.e., steel piles) for support of riverside, or reservoir structures, etc. In fresh water distribution systems, cast iron (historically graphitic iron, recently nodular ductile iron) is more commonly used as a pipe

material as opposed to steel; increasingly polymeric materials are now being used for water systems.

Corrosion problems of ferrous materials in domestic waters are a continuing problem.<sup>144</sup> In 1975, Larson comprehensively surveyed corrosion of steel in fresh water with data gathered from over 30 years of research in Illinois.<sup>145</sup> He developed a classification of waters for corrosion of steel in terms of dissolved oxygen, pH, and dissolved salts, Table 17.

The classification in Table 17 assumes no significant effects from microbial corrosion. In practice, however, microbial effects are ubiquitous and it cannot be assumed that they will always be dealt with satisfactorily by disinfection (e.g., chlorination).<sup>146</sup> However, in potable water systems, where fluid flow is significant, microbial problems are more commonly considered in the industry to affect drinking water quality (e.g., odors and discolouration of the water) than corrosion. Fire protection systems (i.e., risers and sprinklers), on the other hand, in effect comprise a series of stagnant sections in which microbial growth can proliferate. Consequently, microbiologically influenced corrosion is a significant risk in these and similar systems. It is generally advisable to minimize the risk by thorough initial cleaning of new systems in order to remove internal debris as well as hydrocarbons that may comprise a food source. Following cleaning, appropriate (i.e., not too frequent) test schedules should be undertaken in order to reduce the ingress of fresh water. In severe cases, it may be necessary to dose the system with biocides in order to reduce the microbial load.<sup>147</sup>

### 3.01.5.3.3 Structural steel in waters

A major application for unprotected steel in water is in retaining walls (revetments) along river banks, in sea walls, docks and harbors, structural pilings, etc. Particularly in river systems with low salinity, unprotected revetments are traditionally used and have an adequate life. The higher conductivity of saline and sea water permits the option of applying cathodic

**Table 17** Classifications for corrosivity of fresh water

Type of water	Corrosivity
Distilled water, no oxygen	Corrosion is negligible
Mineral salts present, oxygen and carbonate absent	Similar to previous case provided oxygen is kept out of the system
Distilled water and oxygen present	Corrosion rate decreases with increase in pH but danger of severe pitting corrosion if the steel has marginal passivity; danger of localized corrosion in crevices, under deposits and at the water line
Mineral salts and oxygen present, carbonate absent	Increased corrosion compared with distilled water due to higher conductivity; increased tendency for localized corrosion where passivity is marginal
Carbonate, mineral salts and oxygen present, calcium absent	In the absence of $\text{Ca}^{2+}$ , carbonates act to inhibit corrosion with their maximum effect appeared at more than 5–10 times the concentration of other salts ( $\text{Cl}^-$ or $\text{SO}_4^{2-}$ , etc.) at $\text{pH}$ 6.5–7
Dissolved calcium and carbonate present, oxygen present or absent	Significant reduction in corrosion rate if a carbonate scale is deposited, however this does not generally happen unless there is significant supersaturation of $\text{CaCO}_3$ at the pH of the water

Source: Larson, T. E. *Corrosion by Domestic Waters*, Bulletin 59; Illinois State Water Survey, 1975.

protection. However, designs often still rely on a corrosion allowance for unprotected steel. As noted above, although this strategy has worked well in the past, increasingly the use of thinner and higher strength steels is reducing the overall time to perforation. Additionally, increasing corrosion problems are being observed worldwide where severe corrosion of steel piles, retaining walls, etc. occurs at and just below the waterline. This phenomenon was observed from the 1970s onwards in sea water installations<sup>148</sup> and termed ‘marine low-water corrosion’<sup>149</sup>; it also occurs in saline and estuarine locations as well as in fresh water at inland docks (e.g., on Lake Superior, USA).<sup>150</sup>

In marine locations, this corrosion is now called ‘accelerated low-water corrosion’ (ALWC). It manifests itself as severe attack leading to premature failure of steel structures with unusually high rates of corrosion (i.e.,  $0.3\text{--}1\text{ mm year}^{-1}$  compared with expected rates of  $50\text{--}100\text{ }\mu\text{m year}^{-1}$ ). ALWC occurs at or close to the lowest astronomical tide and, hence, is only visible a few times per year and easily missed. The corrosion typically affects only a small percentage of the exposed surface area with a characteristic damage pattern that depends on the particular geometry and pile design.<sup>70</sup> The causal agent for ALWC appears to be a characteristic microbial colonization of the steel surface resulting in biofilms that contain synergetic populations of sulfur reducing and sulfur oxidizing bacteria. Laboratory *in vitro* studies found that an approximate ten-fold increase in corrosion rate for such colonization, similar to that observed in practice.<sup>151</sup> Control of ALWC in existing installations is probably best carried out by a combination of

sterilization of the marine muds combined with cathodic protection. Future installations are recommended to employ cathodic protection in the design (possibly combined with coating) in order to avoid the problem in the future.

#### 3.01.5.3.4 Variation of corrosion with height

The corrosion rate of steel will vary as a function of height above and below the water as the environment changes from predominantly atmospheric, through the splash zone, into water-saturated mud and eventually to an underground condition. In addition to the variation in environment, the available oxygen concentration will also vary with depth. Consequently, differential aeration corrosion is possible where an enhanced zone of corrosion occurs at the location of lowest oxygen concentrations (i.e., the anode becomes localized away from areas of higher oxygen concentration. **Figure 20** shows the variation in remnant thickness as a function of height.<sup>149</sup> The maxima in the corrosion rate are seen to occur in the splash zone immediately above mean high water and at just below mean low water. The former is due to rapid corrosion in intermittently wetted areas (similar to atmospheric corrosion on a surf beach) while the latter is due differential aeration corrosion. Note that the corrosion rate decreases as the pile depth increases into the mud/soil below the water line.

#### 3.01.5.4 Process Waters

##### 3.01.5.4.1 Heating and cooling systems

Corrosion in water systems that are used for process heating/cooling or space heating/air-conditioning is

**Figure 20** Thickness loss as function of height in a piled steel dockside. Reproduced from Morley, J. *Struct. Survey* **1989**, 7(2), 138–151.

inevitable unless care is taken to condition the water environment. The principles for the control of corrosion, scaling and fouling in such systems are all well-known and summarized briefly in [Table 18](#). They are discussed in more detail in the relevant chapter in this book.

In cooler waters, control of the microbiology is essential in order to achieve an effective system. Where the oxygen concentration is controlled at a relatively low level in order to limit corrosion, then anaerobic species are of concern. These include the sulfur reducing bacteria that produce sulfides in solution, which can be of concern due to the formation of unstable sulfide films on steel resulting in pitting corrosion. The presence of nitrate/nitrite reducing bacteria is of concern where nitrite corrosion inhibitors are present since these species will metabolize nitrite and reduce its concentration. Iron oxidizing bacteria can also be problematic due to their oxidation of dissolved ferrous species to ferric, resulting in enhanced deposition of rust deposits throughout the systems.

**Table 18** Summary of main water treatments that are used to limit corrosion and related problems

Treatment	Effect
Water conditioning	Use of pH control, deaeration, softening and deionizing to pretreat the water supply and render it less likely to cause scaling and corrosion
Scale inhibition	Chemical addition made to prevent or modify the deposition of scales particularly on heat-transfer surfaces
Corrosion inhibition	Chemical addition made to reduce the rate of corrosion of metallic materials in the system
Microbial control	Chemical addition made to restrict microbial growth, essential where the water does not exceed sterilization temperatures (i.e., <60–70 °C)

#### 3.01.5.4.2 Boiler waters

The principles of water treatment for the control of corrosion in boilers and related equipment are rather similar to those for heating and cooling systems (except for the absence of microbial corrosion since the water should be sterile) and are also well-established.<sup>152</sup> Clearly the main purpose of boiler water treatment is to maintain the lowest practical corrosion rate at reasonable cost. Traditional water treatment commonly attempts to maintain the steel in the passive region where magnetite is the stable phase and this is achieved by a combination of controlled pH, dissolved oxygen concentration, dissolved salts and addition of inhibitors for corrosion control not just in the boiler but also in the steam lines and condensers. The interested reader is directed to the chapter on boiler corrosion and its control in this book.

### 3.01.6 Underground Corrosion

#### 3.01.6.1 Controlling Factors

In practice, bare carbon steel is rarely exposed underground without some form of functional corrosion protection system. Thus, cathodic protection is universally applied for the protection of buried metal underground almost always in combination with an effective protective coating system. Indeed, the performance of coating systems has been improved to such an extent that only a few milliamps of current per kilometer of buried pipeline might be required for adequate protection. Of course, the improvement in coatings (essentially a reduction in coating permeability to water and ions) leads to its own problems in

the shielding of protection currents where defects exist. The control of corrosion underground, including the influence of stray currents, is dealt with in more detail elsewhere and will not be considered further here.

Regarding the corrosion of buried steel, the seminal contributions from the 1950s and early 1960s of Romanoff in the USA<sup>153</sup> and Hudson in UK<sup>154</sup> for samples buried in some cases since the 1930s, still comprise the standard reference data for underground corrosion of bare, unprotected steel and other metals. Such data are of interest in situations where unprotected steel is used underground, which typically arise in construction applications where the use of steel for piles, revetments, shoring, etc. is not uncommon. More recent interest arises from the possible use of carbon steel as a cladding material for nuclear waste containers where knowledge of the long-term corrosion is essential for development of the relevant safety cases. In these cases, it is of merit to study the corrosion of buried archaeological artefacts as they are the only method for determining very long-term corrosion rates with any degree of certainty.

A detailed discussion of the effects of soil on corrosion of unprotected bare steel is beyond the scope of this article and the interested reader is directed to the relevant chapter on corrosion in soils in this book. In brief, soils vary greatly in corrosiveness according to their aeration, conductivity, composition, and microbial activity.<sup>155</sup> In general, dry, sandy, or calcareous soils, with a high electrical resistance, are the least corrosive. At the other end of the scale are the heavy clays and the highly saline soils, whose electrical conductivity is high. The depth of the water table is also important; much depends on whether the buried iron or steel is permanently above or below this, or even more perhaps on whether it is alternately 'wet' or 'dry.' The variation in corrosion rate with depth of burial is illustrated by the historic results quoted in **Table 19**, which also serve to indicate the rates of average general penetration in typical British soils.<sup>156</sup> It will be noted that the depth of burial had no consistent effect, which is not surprising since the average depth of the water table and the seasonal fluctuations in this varied from one site to another. Bacterial activity often plays a part in determining the corrosion of buried steel. This is particularly so in waterlogged clays and similar soils, where no atmospheric oxygen is present as such. If these soils contain sulfates, for example, gypsum and the necessary traces of nutrients, corrosion can occur under anaerobic conditions in the presence of sulfate-reducing bacteria. One of the final products is iron

**Table 19** Corrosion of mild steel in various soils and depths over 5 years

Site	Type of soil	Average general penetration ( $\text{mm year}^{-1}$ )	
		1.37 m	0.6 m
Benfleet	London clay	0.0185	0.0361
Gotham	Keuper marl	0.0132	0.0094
Pitsea	Alluvium	0.0353	0.0284
Rothamsted	Clay with flints	0.0201	0.0213

Source: Romanoff, M. Corrosion of steel piling in soils, National Bureau of Standards Monograph no. 58 (October 1962).

sulfide, and the presence of this is characteristic of attack by sulfate-reducing bacteria, which are frequently present.

The maximum corrosion rate reported in tests carried out in the USA was  $\sim 70 \mu\text{m year}^{-1}$ ,<sup>153,157</sup> while the maximum rates obtained in tests carried out in the UK were between 35 and  $50 \mu\text{m year}^{-1}$ .<sup>156</sup> However, the localized corrosion was much greater, with maximum rates of  $250 \mu\text{m year}^{-1}$  reported from American, and  $300 \mu\text{m year}^{-1}$  from British, tests.

### 3.01.6.2 Corrosion of Buried Steel

#### 3.01.6.2.1 Piling

Unprotected steel is frequently used in construction as pilings for foundations and soil retention. This is because any protective coating is almost certainly going to be removed by abrasion during the piling operations. Generally, undisturbed soil and earth should have relatively low oxygen content and, hence, steel should have a relatively low corrosion rate. As noted above, **Table 19**, corrosion rates in a variety of different undisturbed soil types are indeed generally quite low, from  $\sim 10$  to  $35 \mu\text{m year}^{-1}$ .

Examinations of steel pilings recovered after considerable times of exposure have confirmed that the average corrosion rate is indeed acceptably low. Romanoff's study in the USA found that the load-bearing capacity of the pilings was not compromised.<sup>158</sup> Studies in the UK on pilings removed from the ground after up to 85 years service found that they were in excellent condition with an estimated average corrosion rate of the order of  $10 \mu\text{m year}^{-1}$  with occasional rates up to  $30 \mu\text{m year}^{-1}$ .<sup>159</sup> On the land (fill) side of piled harbor walls (i.e., in disturbed soil) the corrosion rates were about twice those found for undisturbed soil, but this is still

relatively low. A systematic study in Japan over 10 years showed that the corrosion of piles was not linear with time but was initially high and tended to decrease after time to a long-term rate that was  $\sim 10 \mu\text{m year}^{-1}$ .<sup>160</sup> In Australia, 52 year-old piles from Port Adelaide were removed and the average corrosion rate below the mud line was found to be  $\sim 30 \mu\text{m year}^{-1}$ .<sup>161,162</sup> What also seems clear from this historic data is that microbial corrosion did not seem to be of a significant risk provided the soil was undisturbed.<sup>149</sup>

### 3.01.6.2.2 Pipelines

Buried pipe, whether of steel or cast iron, are invariably coated and additionally protected by a cathodic protection system. It is not proposed to discuss this topic further here except, for completeness, to note the occurrence, during cathodic protection, of intergranular stress corrosion cracking in carbonate–bicarbonate environments and transgranular stress corrosion cracking of higher strength pipeline steels at neutral pH.

### 3.01.6.2.3 Long-term burial

Research on the nature of corrosion product layers on historic buried artefacts is an important component in understanding the progress of corrosion and in the modeling of proposed nuclear waste repositories. Most repository designs comprise a multibarrier system that consists of immobilized (e.g., vitrified) nuclear waste packed into a metallic container that is, in turn, emplaced into a suitable geological repository and backfilled with clay buffer layer. This design is expected to be initially relatively oxidizing (aerated) but will eventually become anaerobic. Since the function of the metal container is to prevent contact between the groundwater and the radioactive wastes for as long as possible, knowledge of the corrosion processes, including the expected corrosion products likely to form, are essential in order to provide a credible model of long-term corrosion over hundreds to thousands of years.

In the United Kingdom, historic iron commonly arises from the period of Roman occupation and later, with the most frequent artefact comprising iron nails. In Europe, buried iron can be found from much earlier. Commonly identified corrosion products include all those that might be expected to form, **Table 4**. In most buried environments the corrosion sequence commences with the development of ‘green rusts,’ which are mixed oxy-hydroxides of iron containing Fe (+2/+3) species and incorporating typically, carbonate, chloride or sulfate depending on the

environment.<sup>163</sup> Generally, depending on local conditions of aeration and pH, this oxidizes further to form magnetite, maghemite, lepidocrocite or goethite; while in high chloride (e.g., marine) environments, akaganéite also forms. In anaerobic, waterlogged, conditions at higher pH (carbonated), siderite (iron carbonate) is a common corrosion product,<sup>164</sup> while at lower pH, vivianite (hydrated iron phosphate) has occasionally been observed.<sup>165</sup>

<b>3.02.1</b>	<b>General Introduction</b>	1739
3.02.1.1	White Cast Iron	1739
3.02.1.2	Gray Cast Iron	1739
3.02.1.3	Malleable Cast Iron	1740
3.02.1.4	Ductile Cast Iron	1740
3.02.1.5	Alloy Cast Irons	1740
<b>3.02.2</b>	<b>Production, Composition, and Microstructural Effects</b>	1740
3.02.2.1	Effect of Microstructure on Corrosion Resistance	1741
3.02.2.2	Influence of Galvanic Couples in the Microstructure	1743
<b>3.02.3</b>	<b>General Corrosion Behavior</b>	1743
3.02.3.1	Low-Alloy Lamellar or Spheroidal Graphite Cast Irons	1743
3.02.3.2	High-Alloy Cast Irons	1744
3.02.3.2.1	Austenitic nickel cast iron	1744
3.02.3.2.2	High chromium cast iron	1746
3.02.3.2.3	High silicon cast iron	1746
3.02.3.3	Typical Applications	1747
3.02.3.3.1	Unalloyed cast irons	1747
3.02.3.3.2	Alloyed ferritic cast irons	1748
3.02.3.3.3	Austenitic cast irons	1748
<b>3.02.4</b>	<b>Corrosion Environments</b>	1750
3.02.4.1	Atmospheric Corrosion	1750
3.02.4.1.1	Nickel cast irons	1750
3.02.4.2	Corrosion in Natural Water	1752
3.02.4.2.1	Introduction	1752
3.02.4.2.2	Aggressiveness and corrosiveness of water	1752
3.02.4.2.3	Influence of dissolved oxygen	1753
3.02.4.2.4	Corrosion of cast Iron in natural water	1754
3.02.4.2.5	Galvanic corrosion of cast iron in natural water	1756
3.02.4.2.6	Inhibition of corrosion in water	1757
3.02.4.3	Corrosion in Steam	1757
3.02.4.4	Corrosion in Seawater	1758
3.02.4.5	Soil Corrosion	1760
3.02.4.6	Methods of Protection	1762
<b>3.02.5</b>	<b>Corrosion in Industrial Environments</b>	1763
3.02.5.1	Sulfuric Acid	1763
3.02.5.2	Hydrochloric Acid	1765
3.02.5.3	Nitric Acid	1765
3.02.5.4	Phosphoric Acid	1765
3.02.5.5	Other Mineral Acids	1766
3.02.5.6	Organic Acids	1766
3.02.5.7	Corrosion by Alkalis	1767
3.02.5.8	Salt Solutions	1768
3.02.5.9	Corrosion–Fatigue	1768
3.02.5.10	Stress Corrosion Cracking	1770
3.02.5.11	Organic Compounds	1772

---

3.02.5.11.1	Alcohol and glycol	1772
3.02.5.11.2	Corrosion by food products	1773
<b>3.02.5.12</b>	<b>Corrosion by Molten Materials</b>	1773
3.02.5.12.1	Corrosion by liquid aluminum or aluminum alloys	1773
3.02.5.12.2	Corrosion by liquid zinc and zinc alloys	1774
3.02.5.12.3	Corrosion by other liquid metals	1774
3.02.5.12.4	Corrosion by liquid sulfur	1774
<b>3.02.5.13</b>	<b>Microbially Influenced Corrosion</b>	1774
3.02.5.13.1	Iron oxidizing bacteria	1775
3.02.5.13.2	Sulfate-metabolizing bacteria	1775
3.02.5.13.3	Mechanisms of action	1775
3.02.5.13.4	Microbial corrosion of cast iron	1775
3.02.5.13.5	Combating microbial corrosion	1776

## Glossary

**Cast iron** An alloy of iron with >1.7% carbon and including appreciable amounts of silicon and other elements. Compared with carbon steel, cast iron has a relatively low melting point and high fluidity permitting it to be cast into complex shapes.

**Ductile or SG iron** A form of cast iron in which the carbon is present as nodular spheroids of graphite and, consequently the iron is ductile.

**Durichlor** A high-silicon iron containing a minimum of 14.5% silicon with additions of chromium and molybdenum and optimised for service in hydrochloric acid.

**Duriron** A high-silicon iron containing a minimum of 14.5% silicon exhibiting extreme abrasion resistance and chemical resistance in acids.

**Gray or LG iron** A form of cast iron with a relatively high silicon content (> ~2%) in which the carbon is present as lamellar graphitic (LG) flakes; generally gray iron is brittle and fails with little or no ductility.

**Hypersilid** A high silicon iron containing from 14–18% silicon and similar to Duriron in performance and usage.

**Malleable Iron** A form of white cast iron that is traditionally produced by subjecting a casting to extended periods of heat treatment, this results in the nucleation of graphite in a nonlamellar form and, consequently, the iron is ductile (malleable).

**Ni-Resist** A form of cast iron containing sufficient nickel such that the iron is able to retain the austenite phase structure at room temperature, consequently, Ni-Resist is heat-resistant and relatively corrosion resistant compared with LG or SG irons.

**White iron** A form of cast iron of relatively lower silicon content in which the carbon is present as carbides and, consequently, white iron is extremely hard and abrasion resistant.

### 3.02.1 General Introduction

Cast iron is the term applied to a wide range of ferrous alloys, whose principal distinguishing feature is carbon content in excess of  $\sim 1.7\%$ . Cast iron can also be thought of as a composite material consisting of precipitated graphite or carbide particles in a metal matrix. The two major types of graphite morphology are flake, associated with gray iron and spherical (nodular), associated with ductile iron. While the properties of steel grades are determined (in addition to the composition) primarily by thermo-mechanical treatment, the properties of cast iron are controlled by inoculation, solidification, and cooling rate as well as alloy composition.

Four main types of iron are commonly encountered:

- white iron in which all the carbon is present in a metal carbide phase;
- gray iron in which most of the carbon is present as graphite flakes;
- nodular or ductile iron in which most of the carbon is present as graphite nodules, produced during solidification of the casting; and
- malleable iron in which most of the carbon is present as graphite nodules, produced subsequent to solidification by heat treatment of the casting.

Many properties of cast iron are first influenced by the form in which the carbon is present; that is, as graphite or as carbide and secondly by whether the matrix material is ferritic or pearlitic.

#### 3.02.1.1 White Cast Iron

In white iron, carbon is in the form of iron carbide in a matrix of pearlite, the amount of which depends on the carbon content of the iron; such materials are hard and brittle. Alloying of white iron is possible and results in the formation of alloy carbides that are even harder and ideal for hard and abrasion-resistant applications such as extrusion dies and cement mixer liners.

#### 3.02.1.2 Gray Cast Iron

Gray cast irons are by far the oldest and most common form of cast iron. Gray iron, named because of its characteristic fracture surface, has a gray appearance and consists of carbon in the form of flake graphite in a matrix consisting usually of pearlite or ferrite or a mixture of the two. The fluidity of liquid gray iron and its expansion during solidification due to the formation of graphite, has traditionally been ideal for the economical production of shrinkage-free, intricate castings such as motor blocks. These alloys are often known as lamellar graphitic (LG) cast irons; a sketch of the typical arrangement of lamellar graphite is shown in [Figure 1](#).

Gray iron exhibits essentially no elastic behavior, and fails under tension without significant plastic deformation. The mechanical properties of gray cast iron result from the effects of chemical composition and the cooling history. In general, as the combined equivalent of carbon and silicon is reduced the strength of the cast iron is increased. For thicker sections requiring tensile strengths above 350 MPa, additions of chromium, nickel or molybdenum alloys are required.

The presence of graphite flakes gives gray iron an excellent machinability, damping, and self-lubricating characteristics. Consequently, gray cast iron has an outstanding resistance to sliding wear and has been used very successfully for sliding surfaces including cylinder bores, piston rings, and machine tools. Due to the effect of the graphite flakes, gray cast iron has an excellent resistance to galling and seizing, and has a low coefficient of friction. Finally, gray cast irons have an excellent capacity for absorbing

**Figure 1** Sketch of lamellar (flake) graphite in cast iron.

vibration energy, and thus damping vibrations. This property is most evidenced with those materials with a high percentage of graphite flakes.

### 3.02.1.3 Malleable Cast Iron

Malleable irons are initially manufactured as white irons and subsequently heat treated in order to convert the carbide into graphite, which nucleates and grows from individual locations giving a more compact, nonlamellar form. Malleable irons are produced by two different processes, which result in either a ferrite or a pearlite matrix depending on the process adopted; however, even the pearlitic form is usually produced with a surface layer of ferrite. In malleable irons, the presence of graphite in a more compact or sphere-like form gives the material greatly increased ductility with tensile and yield strengths almost equal to cast, low-carbon steel.

### 3.02.1.4 Ductile Cast Iron

Ductile cast irons are similar to gray cast irons but have small amounts of alloying addition (e.g., magnesium) that promote the formation of carbon in a nodular form rather than as graphite flakes; they are often known as spheroidal graphitic (SG) irons or nodular graphitic irons; a schematic microstructure is shown in [Figure 2](#). Ductile iron generally solidifies with a pearlite matrix, but in order to develop the full ductility of the iron, the castings are often subsequently annealed to give a ferrite matrix. They have properties similar to that of gray irons with a relatively low melting point (compared with steels), good

**Figure 2** Sketch of spheroidal graphite in cast iron.

fluidity, castability, excellent machinability, and wear resistance. However, compared to gray cast iron they have improved strength, toughness, and hot workability. Moreover, the nodular forms of graphite result in greatly increased fracture toughness and offer the designer the option of choosing high ductility (with some grades guaranteeing more than 18% elongation), or high strength (with some tensile strengths exceeding 800 MPa).

### 3.02.1.5 Alloy Cast Irons

The properties of both white and gray cast irons can be altered and enhanced by the inclusion of alloying elements such as nickel, chromium, molybdenum, and silicon. For example, 4–5% nickel and 1.2% chromium additions are used to increase hardness and mechanical properties. Alloys containing over 14–25% nickel, are austenitic and have good heat and corrosion resistance. Alloys with 25–35% chromium result in a ‘stainless’ cast iron with good corrosion and high temperature properties, while irons containing up to 16% silicon offer enhanced hardness and excellent corrosion resistance at the expense of mechanical properties.

## 3.02.2 Production, Composition, and Microstructural Effects

A cast iron is an alloy of iron that contains 2–4% carbon, along with varying amounts of silicon and manganese and traces of impurities such as sulfur and phosphorus. The relatively low melting point of these alloys compared with that of steel and their tendency to expand slightly on solidification, which make them admirably suitable for the production of components by casting, result from this feature of their composition. The production of cast iron is relatively unsophisticated and mostly involves remelting charges consisting of pig iron (e.g., from a blast furnace), steel scrap, foundry scrap, and ferroalloys to give the appropriate composition. The composition figures quoted in [Table 1](#) provides a general guide for the range of compositions for the various types of iron. Due to this variation in composition, cast irons are usually specified in terms of their mechanical properties rather than on an analytical basis. Cast iron is used extensively to make machine parts, engine cylinder blocks, stoves, pipes, steam radiators, and many other products.

**Table 1** Composition ranges of cast iron alloys (nodular iron additionally: 0.04–0.1% Mg)

	Microstructure		Carbon (%)	Carbide (%)	Si (%)	Mn (%)	S (%)	P (%)
	Graphite	Matrix						
White iron	None	Pearlite	1.7–3.0	100%	0.8–1.3	0.4	<0.15	<0.5
Gray iron	Flake	Pearlite	2.7–4.0	<1	0.5–3.3	0.3–1.0	<0.15	<1.4
Nodular	Nodular	Pearlite/ferrite	3.3–3.9	<1	1.6–2.5	0.4	<0.01	<0.1
Malleable (blackheart)	Nodular	Ferrite	2.0–2.7	None	0.8–1.2	0.1–0.6	<0.15	<0.2
Malleable (whiteheart)	Nodular	Pearlite	3.3–3.9	0–1	0.3–0.8	0.1–0.5	<0.4	<0.1

### 3.02.2.1 Effect of Microstructure on Corrosion Resistance

The essential difference between the corrosion of cast iron and steel arises from the fact that cast iron contains in its microstructure several more or less corrosion-resistant phases that are largely or completely absent from steel. The most important of these corrosion-resistant phases are: graphite, phosphide eutectic, and, to a lesser extent, carbides, and carbide eutectic (i.e., pearlite). A close observation of the corrosion products of cast iron<sup>1</sup> can distinguish two distinct layers (see Figure 3).

The base layer, exactly occupying the place and volume of the original corroded metal and hence, sometimes called the 'topotaxial layer,' contains the inert, noncorroding elements of the cast iron, the graphite, in particular, possibly the phosphorous eutectic, and a few carbides for which the initial shape and distribution are preserved. The pores resulting from the selective attack of the ferrous matrix are generally filled by corrosion products of iron; additionally, the oxidation products of silicon (e.g., silicic acid) contribute to cohesion. This layer, which has no equivalent in steel, is often called the layer of 'graphitic corrosion residue.' This is because the species it contains, and which can most readily be identified (by X-rays), is graphite. This also explains terms such as graphitosis, graphitization, graphitic, or spongy corrosion, etc, that are often used to describe this form of corrosive attack.

The outer surface layer (epitaxial layer), which develops from the initial surface of the iron casting, results from the reaction of iron ions ( $\text{Fe}^{2+}$ ), migrating through the graphitic layer from the underlying residual metal. This layer often takes the form of a voluminous gangue (up to 3.7 times the volume of iron lost to corrosion). It may also contain elements from the corrosive environment, either by

**Figure 3** Schematic diagram showing layers of corrosion on gray cast iron. Based on a diagram by Tsuda M.; Murata Y., *IMONO, 1982, 54, 605–611* and reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

incorporation, in the case of a solid aggressive medium (case of soils), or by precipitation, in the case of a liquid aggressive medium (e.g., calcareous rust). This layer (which has some protective capacity), thus, has variable density depending on the nature of the surrounding medium. Also, the layer may not even exist if the products of the reaction between the iron and the corrosive medium can be eliminated as they form, for example by an erosive action, or if they are immediately soluble.

These two layers are clearly distinct in both appearance and composition; one contains essential corrosion residues, while the other contains corrosion products. They can be separated more or less readily from one another (by scraping or as a result of an impact). Thus, after elimination of the outer layer of corrosion products, the casting most often appears in its initial form and may mask the actual extent of corrosion damage, which can be revealed only by sand blasting or by special measurements (ultrasound). The layer of corrosion products, consisting essentially of various hydrated iron oxides, is rather similar to the layer of

corrosion products that would form under the same conditions on steel.<sup>2</sup> However, it is anchored in a very different manner: in the case of steel, this layer develops from the evolving active corrosion front, while in the case of a cast iron, it develops on the unchanging inert surface of the layer of corrosion residues.

These layers, in particular the layer of corrosion residue, also act as a barrier that retard the progress of corrosion, as can be seen from the schematic representation (Figure 4) of the corrosion of a cast iron and of a steel in an acid medium: the graphite, highly cathodic with respect to the iron in an acid medium, at first speeds up the corrosion, then slows it by a barrier effect that limits the exchange between the acid medium and the corrosion front.

The amount of graphitic residue retained on a corroding surface depends partly on the morphology of the graphite and partly on the corrosivity of the medium. In general, coarse flake graphite tends to give a more permeable and less strong residue than finer graphite, while nodules produce an even weaker residue. However, these differences are only clear at very high corrosion rates. For example, while flake graphite iron retains virtually all the graphitic residue when corroded in 0.5% sulfuric acid, the residue from a nodular graphite iron is largely detached; in 0.05% sulfuric acid, however, there is little difference in the amounts retained by the two irons. Also, the effect of graphite on the corrosion of iron depends on the residue thickness – thus in 0.5% acid, graphite stimulates attack on the nodular graphite iron because of its ability to act as an efficient cathode for hydrogen evolution, however, in 0.05% acid, once the residue thickness reaches  $\sim 0.1$  mm, the attack tends to become stifled.<sup>3</sup>

**Figure 4** Schematic representation of the corrosion of a cast iron and of a steel in an acid medium. Based on a diagram by Hasson, D.; Karmon, M. *World Water*, 1983 (November), 44–45 and reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

Also note, that the original geometry of the material is often preserved after graphitic corrosion, unless the corrosion products disintegrate, and that the mechanical strength of this graphitic residue is generally good (especially if the graphite is lamellar). For example, water pipes made of graphitic cast iron, although severely corroded after  $\sim 30$  years in service can still withstand high water pressures. However, ductile iron or steel pipes have burst under similar conditions. Similarly, some cast iron water pipes of the Château of Versailles are still functioning properly more than three centuries after they were installed (see Figure 5).

If the graphite form is spheroidal, the layer of graphitic residue is more friable and mechanically less strong because it receives less support from remaining graphite, which is distributed discretely, rather than continuously. On the other hand, the noncontinuity of graphite in SG cast irons also limits the penetration of the corrosion front, which occurs preferentially at the matrix–graphite interface. Otherwise, the often higher silicon content of spheroidal graphite cast iron implies, that the proportion of silica in the graphitic corrosion residue is slightly

**Figure 5** Length of lamellar graphite cast iron water pipe in Versailles (more than three centuries old). Reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

larger in these materials. Despite these factors, it is important to remember that the slight benefits given by improved mechanical strength of the graphitic residue in lamellar graphite iron must not lead us to overlook the considerable superiority of the mechanical properties of spheroidal graphite cast iron.

### 3.02.2.2 Influence of Galvanic Couples in the Microstructure

In the case of cast iron, an eminent heterogeneous alloy, there is apparently an involvement of the galvanic couples that exist between the various metallographic phases. In addition to the couples formed with graphite (which is inevitably the cathode), they include, for example, the iron carbide–ferrite and iron phosphide–ferrite couples, which lead to the selective preferential dissolution of the ferrite (because cementite and iron phosphide are relatively noble).

Residues of islands of pearlite and coalesced carbides, after a ferritizing heat treatment of SG cast irons, can also lead to the formation of very fine microcells. This can result in the complete removal of the ferrite matrix, leaving the carbides, the phosphorous eutectic, and in particular the graphite in the corrosion products. Research has shown that SG cast iron has a higher susceptibility to corrosion than LG cast iron because of the magnesium sulfide inclusions (magnesium is used to inoculate the casting to promote formation of graphite nodules).<sup>4,5</sup> A Japanese electrochemical study<sup>6</sup> showed that, in the case of spheroidal graphite cast irons, the resistance to corrosion decreases as the size of the spheroids decreases. In the special case of SG cast irons obtained by stepped quenching, a bainitic microstructure results. The effect of graphite morphology on the corrosion resistance of this type of iron, austempered ductile iron (ADI) as defined for example by European standard BS EN 1564:1997, has shown, by corrosion potential measurements and anodic polarization tests, that in a 0.01 M HCl, the size of the graphite spheroids has little effect on corrosion resistance. Otherwise, corrosion resistance is diminished as the duration of the stepped quenching increases.

Researchers<sup>6</sup> have also studied the corrosion behavior of ADI cast irons as a function of nickel content and of the chill effect. The corrosion tests, in a 1 N NaCl solution, lasted from 12 to 72 h. Mass loss experiments showed that increasing the nickel content increased the corrosion resistance (especially at the longest test duration). The specimens taken in the vicinity of the chill had a greater corrosion resistance, which was attributed to a particular

carbide content. Finally, this study reported that the corrosion resistance of ADI cast iron is superior to that of classical pearlitic cast iron.

## 3.02.3 General Corrosion Behavior

### 3.02.3.1 Low-Alloy Lamellar or Spheroidal Graphite Cast Irons

Apart from silicon, small variations in the composition of cast irons, or even the addition of minor amounts of alloying elements, generally have little effect on the corrosion resistance. This is illustrated by the work of Graham,<sup>7</sup> which related the corrosive wear of automobile cylinders and piston rings exposed to high sulfur fuels. Thus, iron exposed to 70% sulfuric acid at 130 °C is attacked at rates dependent on its silicon content, the rate being relatively low at below 1% Si but rising to a peak at ~2% Si (Figure 6).

Whittaker and Brandes<sup>8</sup> followed up this work, carrying out tests on iron containing small amounts of copper and nickel. The addition of 0.6% Cu to iron containing 2% Si improved the corrosion resistance significantly, but made little difference, or was detrimental, to iron containing less than 1.5% Si. Copper additions also appear to reduce the effect on corrosion of the sulfur content of an iron exposed to acid and the effect is thus lower in low sulfur irons. Since sulfur can stimulate corrosion in acidic

**Figure 6** Weight loss for cast iron exposed in 70% H<sub>2</sub>SO<sub>4</sub> at 130 °C for 16 h. Reproduced with permission from Graham, R.; Prado, O. S.; Collins, M. H.; Brandes, E. A.; Farmery, H. K. *Proc. Inst. Mech. Eng.* **1960**, 174, 617.

environments, it is usually kept as low as possible in irons to be used under these conditions; a low sulfur content, in any case, generally desirable.

### 3.02.3.2 High-Alloy Cast Irons

Significant additions of such alloy elements as nickel, chromium, and silicon have a great impact on the corrosion resistance of cast irons.<sup>9</sup> They modify the matrix, increasing its corrosion resistance and promote the formation of protective oxide (passive) films. The general outcomes of the most important additions are:

- nickel additions will tend to stabilize austenite;
- chromium cast irons, depending on the levels of chromium, carbon, and other added elements, including nickel, will be ferritic or austenitic;
- silicon cast irons will be ferritic.

#### 3.02.3.2.1 Austenitic nickel cast iron

The addition of ~20% nickel to cast iron produces materials with a stable austenitic structure; these materials are sometimes known as austenitic cast irons but are more often referred to commercially as 'Ni-Resist' cast irons. The austenitic matrix of these irons gives rise to very different mechanical and physical properties compared with those obtained with the nickel-free gray cast irons. The austenitic matrix is more noble than the matrix of unalloyed gray irons, and it was shown in the early work of Vanick and Merica<sup>10</sup> that the corrosion resistance of cast iron increases with increasing nickel content up to ~20% (Figure 7).

Although the Ni-Resist irons, due to their austenitic matrix, are tougher and more shock resistant than the nickel-free gray irons, those with carbon in the lamellar graphite form (LG irons) still exhibit certain disadvantages due to the graphite structure. Much better strength and impact properties can be obtained by treating the iron with a small quantity of magnesium sufficient to give a residual content of 0.05–0.1%, which converts the graphite to a spheroidal form (SG irons). The Ni-containing austenitic irons are thus available in both LG and SG forms. The matrix also contains small amounts of second phase carbides, the quantity of which increases with increasing chromium content.

The first alloys in the Ni-Resist series, containing ~20% nickel, were introduced in the 1930s and soon became established in both corrosion and heat resistant applications. The range of alloys has been

**Figure 7** Effect of nickel content on corrosion resistance of cast iron.

extended over the years with nickel contents varying from 13% to 35%. Each material has a somewhat different characteristic such that the most appropriate grade must be selected to obtain the most advantageous properties for any particular application. The compositions and mechanical properties of the principal grades of austenitic cast irons are summarized in Table 2. There is no spheroidal austenitic iron corresponding to Type 1 Ni-Resist, since it is difficult to obtain a good spheroidal graphite structure in an austenitic iron containing more than 2% copper. A considerable number of modified grades, differing in both composition and properties from the basic grades, also exist. Specifications for eight commonly used grades of austenitic cast irons are given in BS EN 13835:2002.

The tensile strengths of the spheroidal graphite iron are generally about twice as those of their flake graphite equivalents and can be further improved, by ~80 MPa, by quenching the iron in oil or water from temperatures of 925–1000 °C. This treatment is even more effective when applied to chill castings but the resulting ductility is reduced because of the increased amount of carbide formed as a result of chilling. The impact resistance of the spheroidal graphite grades is much better than that of the equivalent flake graphite

**Table 2** Composition and properties of principal grades of flake and spheroidal graphite austenitic case irons

BS 3468 designation	Ni-resist type	Composition (wt%)						Minimum tensile strength ( $\times 10^7 \text{ N m}^{-2}$ )	Brinell hardness
		C	Si	Mn	Ni	Cr	Cu

irons and elongation values as high as 40% can be obtained with the SG irons. The mechanical properties of the austenitic irons are also good at low temperatures and can be useful in a number of chemical plants and cryogenic applications.

The austenitic irons show excellent casting properties and good machinability, which, in combination with the good mechanical properties and good corrosion resistance, ensures wide use of these materials in many applications.

### **3.02.3.2.2 High chromium cast iron**

There is no clear demarcation between high-chromium steels and high-chromium cast irons other than the fact that components are fabricated from steels, and cast in the irons. In practice, however, irons are usually found to have carbon content varying between 0.6% and 3%, while most of the steels contain less than 0.3% carbon. Of the high-chromium irons, those used for components requiring a high degree of corrosion resistance, normally contain 25–35% chromium. It is established<sup>11</sup> that a useful formula to compute the minimum chromium content of a corrosion-resistant iron is:  $\%Cr = (\%Cr \times 10) + 12$ . That is, increased carbon content requires balancing with increased chromium content in the alloy. For example, a 1.5% carbon alloy should contain not less than 27% chromium.

The limitations imposed by this formula, together with the fact that the alloys in practice rarely contain more than 35% chromium, suggest that the maximum carbon content of the irons should be 2.3%, and that the irons normally contain between 1.0% and 2.0% carbon, unless some property other than corrosion resistance is of prime importance. Silicon may also be present in high-chromium irons in amounts varying between 0.5% and 2.5%; any value more than this has an embrittling effect. Silicon increases fluidity in the foundry and improve the surface quality of castings. Further effects are to refine the eutectic carbides in the iron, to produce a more uniform structure and to raise the temperature at which the matrix transforms from ferrite to austenite with consequent dimensional changes.

Irons with compositions discussed above have structures comprising a uniform dispersion of chromium–iron complex carbides in a matrix of chromium-containing ferrite. The chromium content of the ferrite is not known, although it is assumed to be ~10–13%. The carbides are probably mixtures of the types  $Cr_7C_3$  and  $Cr_{23}C_6$ , in which some of the chromium has been replaced by iron.<sup>12</sup>

In general, the high-chromium irons are hard but not completely unmachinable. Typically, chromium cast irons, of the compositions described above, have tensile strengths ~450–480 MPa and hardness ~350 Brinell. The hardness of these alloys makes them particularly useful in environments where abrasion or wear resistance may be as important as corrosion resistance. However, the principal difficulties in the production of castings in this alloy are its high shrinkage, which entails some tendency to develop porosity, and the ready formation of an oxide skin, which may cause cold laps in the casting. Castings must, in consequence, be produced by methods similar to those employed for steel castings and care must be taken to avoid the introduction of oxide into the mould.

The high-chromium irons undoubtedly owe their corrosion-resistant properties to the development on the surface of the alloys of an impervious and highly tenacious film, probably consisting of a complex mixture of chromium and iron oxides. Since chromium oxide is derived from the chromium present in the matrix and not from that combined with the carbide, it follows that a stainless iron will be produced only when chromium in excess of the amount required to form carbides is present.

High chromium-containing cast irons are most useful in environments containing an abundant supply of oxygen or oxidizing agents; anaerobic or reducing conditions may lead to rapid corrosion since this may detrimentally affect passivity. Physical effects such as abrasion or sudden dimensional changes induced by temperature fluctuations may rupture the film and allow corrosion to take place. The iron will also be subject to corrosion by solutions containing anions, such as those of the halides, leading to pitting corrosion. With respect to mineral acids, the most important characteristic of chromium cast irons is its resistance to nitric acid, especially in dilute solution. On the other hand, these cast irons do not resist alkaline hydroxides and concentrated mineral acids. Ferritic chromium cast irons turn out to have excellent resistance to high temperature oxidation up to 950–1000 °C.

### **3.02.3.2.3 High silicon cast iron**

Up to ~3%, increasing silicon content has little effect upon the corrosion resistance of the cast iron. In alloys containing much greater amounts of silicon, however, the silicon is responsible for the development of a marked increase in chemical resistance. These alloys can be divided into two types: those containing 4–10% silicon, which are used in

applications requiring an iron with good resistance to oxidation at high temperatures, and those containing 12–18% silicon, which are used in applications requiring an iron with very high resistance to acid attack. The latter are commonly referred to as the high-silicon irons. Compositions and mechanical properties of the high-silicon irons are given in Tables 3 and 4.

All these alloys are characterized by high values of hardness and low resistance to impact. Consequently, they are more similar to stoneware than to other metals but are superior to stoneware in thermal conductivity and in their resistance to thermal shock, which, however, is poor compared with that of other metals. Thus, high-silicon irons may be used at elevated temperatures if the process requires it. The principal limitation on their use is imposed by their relatively low thermal conductivities and susceptibility to cracking from thermal shock; this demands that the rate of application or removal of heat should not be rapid.

The microstructure of the high-silicon irons containing less than 15.2% silicon consists of a matrix of silico-ferrite<sup>13</sup> in which a majority of the carbon present in the alloy is distributed as fine graphite flakes. The addition of chromium or molybdenum in the alloy results in the formation of some alloy carbides. The hardness and brittleness of silicon-containing cast iron is predominantly due to the nature of the silico-ferrite, which is intrinsically brittle. Although attempts<sup>14</sup> have been made to produce high-silicon iron with a nodular graphite structure, because of the low strength of these alloys due to the matrix rather than to the graphite form, nodular graphite irons have little, if any, mechanical superiority.

Since the mechanical properties of high-silicon irons preclude any machining other than grinding, it is necessary to cast the materials essentially to net the final shape in such a way that subsequent treatment is kept to a minimum. Also, in view of their poor mechanical properties, the development of any stress in the castings during solidification is very dangerous, since they may cause the casting to crack in

subsequent service. To overcome this risk, it is often desirable to strip the castings from the moulds while they are still red hot and to anneal them at 850 °C for several hours, followed by slow cooling.<sup>15</sup>

### 3.02.3.3 Typical Applications

#### 3.02.3.3.1 Unalloyed cast irons

In spite of competition from other materials, cast iron has an extensive range of applications due to the improving number and variety of properties.<sup>16,17</sup> However, the adaptation of a type of cast iron to a given application calls for analysis and identification of the required properties, which are often very complex, among which the corrodibility and the cost price must in particular be considered. Austenitic cast irons and stainless steels cost roughly four and five times as much as unalloyed cast irons, respectively. These relative costs must be considered in the light of the respective service lives and replacement costs. Otherwise, the differences in properties between lamellar graphite unalloyed cast irons and austenitic cast irons are substantially of the same order as the differences between carbon steels and austenitic stainless steels.

When the service life of a unalloyed cast iron is mediocre, the addition of alloy elements (e.g., nickel, chromium, molybdenum, copper) can often extend it inexpensively. However, it must be borne in mind that possible casting defects (blowholes, porosities, inclusions of silica or slag, shrinkage cavities, irregularities of structure, segregation, undesirable constituents at grain boundaries, etc.) may be the locus of pitting or of local attack that may considerably shorten the life of the castings. Experience has shown that unalloyed iron castings of irreproachable quality and soundness, having a homogeneous structure, prepared using all the resources of the technique, can in some applications have longer service lives than parts made of special cast irons that are more delicate to work, more expensive, and not always free of defects.

**Table 3** Analysis of typical silicon-iron alloys

Name	Total carbon (%)	Si (%)	Mn (%)	S (%)	P (%)	Ni (%)	Cr (%)	Mo (%)

Durichlor	108	Nil	450

**3.02.3.3.2 Alloyed ferritic cast irons**

The addition of chromium allows the use of cast iron in the chemical industry (retorts, tanks, heat exchangers, etc.) where gray iron would have an unacceptably high corrosion rate. The degree of corrosion resistance of a cast iron (with chromium, for example) depends first on the nature of the film or layer that forms on the surface. If this film is dissolved or broken up or is destroyed because of the agitation of the aggressive medium, corrosion continues and can reach unacceptable levels comparable to unalloyed cast iron.

For example, with chromium contents from 12% to 20%, cast iron is satisfactory for the retorts used in the synthesis of carbon disulfide, which are generally exposed continuously to temperatures between 850 °C and 900 °C; their average life is of the order of 6 months.<sup>16</sup> In pyrite furnaces, it is the best material for the production of certain parts, notably because of its good resistance to sour gas ( $\text{H}_2\text{S}$ ) at 1000 °C. The reaction between sodium chloride and concentrated sulfuric acid, producing gaseous hydrochloric acid at high temperature, requires ferritic chromium cast irons for the moving parts of the furnaces.<sup>16</sup> In aqueous corrosion conditions, chromium contents from 25% to 35% are often required to counter the removal of chromium from the matrix by the formation of carbides. If sufficient chromium is present, the cast iron has similar attributes to stainless steel and low corrosion rate when passive but is susceptible to pitting corrosion in chloride media and where oxidizing agents (e.g., cupric and ferric ion) are present in solution. The pitting corrosion of a high chromium cast iron in 4000  $\text{mg l}^{-1}$  chloride ion is shown in Figure 8.

Since the corrosion resistance of the high-silicon ferritic cast iron depends on the permanence and impermeability of a thin silica film on the surface of the metal, it is obvious that any reagent which can

**Figure 8** Potentiodynamic polarization curves for high-chromium white irons in nitrogen-saturated solution containing 4000  $\text{mg l}^{-1}$  chloride at pH 7 and 25 °C. Reproduced with permission from Dodd, J. *J. Mater. Energy Sys.* **1980**, 2, 65–76.

damage the film will cause accelerated corrosion of the metal. For this reason all solutions containing hydrofluoric acid must be regarded as incompatible with the alloys.

Apart from this, high silicon iron offers an excellent resistance to attack by all concentrations of nitric and sulfuric acids and their mixtures. It also provides good performance in hydrochloric acid and in phosphoric acid that is relatively free of fluoride.

Ferritic silicon cast irons (14–18%) are routinely used in parts for contact with acids of all concentrations and for acid effluents. For example, the mixers used to prepare sulfuric acids containing less than 25% water, for the production of explosives and of nitrated derivatives that are themselves used in the production of dyestuffs, are made of silicon cast iron.<sup>16</sup> The thesis by Y. Cetre<sup>18</sup> is a useful source of information about this subject.

**3.02.3.3.3 Austenitic cast irons**

In addition to the ferritic structures produced by additions of silicon or chromium, there is another

major family of cast irons, produced by addition of large quantities of nickel, cast irons having an austenitic structure; their resistance to electrochemical corrosion is much better than that of unalloyed cast irons. Austenitic cast irons show lower corrosion rates than ferritic irons primarily due to the nickel content of the austenitic matrix. Thus, in deaerated sulfuric acid, active dissolution of the austenitic irons occurs at more noble potentials resulting in an intrinsically lower active corrosion rate. Similarly, the critical current density ( $i_{crit}$ ) for passivation of austenitic irons tends to decrease with increasing chromium and silicon content. Thus, austenitic irons, particularly those of higher chromium and silicon content, show superior corrosion resistance compared with ferritic irons.

In paper mills (installations processing pulp and paper), the standard practice is to use austenitic nickel cast irons for equipments operating in solutions of sulfites or sulfates or in caustic solutions. This type of cast iron is also used for parts of furnaces operating at high temperatures and for valves used in sulfuric, phosphoric, and concentrated brines. Spheroidal graphite austenitic cast irons, because of their good ductility and high impact energy, can be specified for vessels containing rather aggressive liquids at high pressures (see standard NF A 32-211 of January 1991)<sup>19</sup> and are also suitable for the production of pumps, valves, and turbo-expanders for low temperature duty in the petrochemical industry, and for the preparation, transport, and storage of liquefied gases.

The individual characteristics and uses of some of the basic grades of the austenitic irons are given in **Table 5**. The major uses of these materials occur in the handling of fluids in the chemical and petroleum industries and also in the power industry and in many marine applications. The austenitic irons are also used in the food, soap, and plastics industries where low corrosion rates are essential in order to avoid contamination of the product. Ni-Resist grades Type 2, 3, or 4 are generally used for such applications but the highly alloyed Type 4 Ni-Resist is preferred where low product contamination is of prime importance.

The modified grades of Ni-Resist are often different from the basic grades used in additional applications. Ni-Resist Types 1B, 2B, and D-2B have a higher chromium content than the corresponding basic grades which increases the erosion resistance of the materials; these grades are less expensive than the other grades with good erosion resistance, that is, Ni-Resist Types 3 and 4. A chromium-free grade of austenitic iron, Ni-Resist Type D-2C, has particularly good ductility and shows good mechanical properties below  $-100^{\circ}\text{C}$ . Even better low temperature properties are, however, obtained with Ni-Resist Type D-2M, a chromium-free 4% manganese grade, which was specially developed for cryogenic applications such as the separation of aromatic hydrocarbons and the production of ethylene. Ni-Resist Type D-4A is a recently developed grade of austenitic iron, which has particularly good resistance to high temperature oxidation and better ductility than the standard Type D-4 grade.

**Table 5** Characteristics and uses of basic grades of austenitic cast irons

<i>BS EN 13835 designation</i>	<i>Ni-Resist Type</i>	<i>Characteristics</i>	<i>Uses</i>
AUS101A	Type 1	Least expensive austenitic iron: good corrosion resistance particularly in acidic media	Pumps, valves, furnace components
AUS102A AUS202A	Type 2 Type D-2	Good corrosion resistance; better than Type 1 in alkaline environments	As for Type 1 but preferable for alkaline solutions; used in soap and plastic industries
AUS105 AUS205	Type 3 Type D-3	Good thermal shock resistance; high resistance to erosion particularly in alkaline media	Pumps, valves, pressure vessels, filter parts, exhaust gas manifolds
— —	Type 4 Type D-4	Best corrosion resistance and erosion resistance of the austenitic irons	Castings for industrial furnaces; used in food industry for low contamination of product
— —	Type 5 Type D-5	Very low thermal expansion; good dimensional stability	Scientific instruments, glass moulds
AUS104 AUS204	— —	Good resistance to high temperature oxidation; good corrosion resistance in sulphuric acid	Pumps and valves

One of the outstanding properties of the austenitic irons is their resistance to graphitic corrosion or 'graphitization.' In some environments, ferritic cast irons corrode in such a manner that the surface becomes covered with a layer of graphite. This compact graphite layer, being more noble than the matrix, markedly increases the rate of attack. The austenitic irons rarely form this graphite layer and consequently, in environments where graphitic corrosion is a problem, perform much better than low-alloy cast irons. Practical experience indicates that the corrosion resistance of the flake and spheroidal graphite irons is similar in many environments; however, the spheroidal graphite irons have shown superior corrosion resistance compared to the equivalent flake graphite grades in a number of cases.<sup>20</sup>

### 3.02.4 Corrosion Environments

#### 3.02.4.1 Atmospheric Corrosion

As cast iron components are normally very heavy in section, the relatively low rates of attack associated with atmospheric corrosion do not constitute a problem and little work has been carried out on the phenomenon. A summary of some data is given in [Table 6](#). The most extensive work in this field was initiated by the American Society for Testing and Materials (ASTM) in 1958 and some of the results produced by these studies are quoted in [Table 7](#).<sup>21</sup> It should be noted that there is a marked fall in corrosion rate with time for all the metals tested.

The atmospheric corrosion rate is generally determined by the atmospheric relative humidity (RH) and degree of air pollutants (i.e., gaseous, dust, and salt aerosols); at RH less than ~65%, atmospheric corrosion rates are usually relatively low. However, in areas of high humidity (above 70% for most of the year), unalloyed cast irons suffer generalized corrosion and results in the formation of rust similar to that in steel; that is, the corrosion product remains on the surface, [Figure 9](#). In such cases, the initial corrosion rates vary from below  $25 \mu\text{m year}^{-1}$  in a pollution-free rural atmosphere to over  $150 \mu\text{m year}^{-1}$  in a polluted atmosphere (i.e., containing  $\text{SO}_2$ ) or a marine atmosphere (i.e., containing sea-salt spray aerosol particles). However, this initial corrosion rate decreases as the duration of exposure increases due to the formation of an adherent and highly protective layer of corrosion product. The main characteristics of the two main types of atmospheric media (indoor and outdoor) are:

Indoors:

- partial pressure of water vapor generally less than the saturated vapor pressure at the same temperature (i.e.,  $\text{RH} < 70\%$ );
- no large variations of temperature;
- very thin films of water on the surfaces of metals;
- relatively low concentration of gaseous and solid pollutants.

Outdoors:

- presence of thick films of water on the surfaces of metals (e.g., rain, etc.);
- level of pollution by acid gases ( $\text{SO}_2$ ,  $\text{NO}_x$ ,  $\text{Cl}_2$ ) generally higher than indoors;
- large variations of temperature (e.g., periodic diurnal temperature variations);
- variation (cyclic or not) of sunshine and of exposure to wind.

The atmospheric corrosion of cast irons is not a very acute problem: in many cases, a simple coat of paint will provide adequate protection. Otherwise, there seems to be rather little difference between lamellar graphite cast irons and spheroidal graphite cast irons; the latter are slightly better in an industrial environment, where the medium is more aggressive, because there is so little corrosion that the differences of behavior are hardly significant. The presence of small amounts of copper tends to improve the resistance of lamellar graphite cast irons to atmospheric corrosion in an industrial environment.<sup>22</sup>

Specific consideration must be given to local industrial environments in a plant that might give rise to more extensive corrosion. Generally,  $\text{CO}_2$  in excess of the normal atmospheric level will not be a problem. However, acid gases or aerosols, such as  $\text{SO}_2$ , sulfuric acid and phosphoric acid (e.g., from industrial plant) and  $\text{H}_2\text{S}$  and  $\text{NH}_3$  (e.g., from sewage works) generally require a highly alloyed material or effective surface protection by an organic coating. Thus, in principle, the atmospheric corrosion of unalloyed or low-alloy irons is similar to steel.

##### 3.02.4.1.1 Nickel cast irons

Although the Ni-Resist irons will not remain rust-free when exposed to the atmosphere, their corrosion resistance is much better than that of plain cast iron or mild steel. The results of a 7.5 year exposure trial carried out in a marine environment at Kure Beach, North Carolina, USA are shown in [Figure 10](#). The corrosion rates derived from the curves after 7.5 years of exposure are given in [Table 8](#).

### 3.02.4.2 Corrosion in Natural Water

#### 3.02.4.2.1 Introduction

Water is a universal solvent for solids, liquids, and gases and, hence, water in its natural form is never chemically pure. It is likely to contain dissolved gases ( $\text{O}_2$ ,  $\text{CO}_2$ ,  $\text{N}_2$ ,  $\text{SO}_2$ ,  $\text{Cl}_2$ , etc.), organic or mineral matter (microorganisms, sand, etc.), and dissolved salts as ions ( $\text{Ca}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Cl}^-$ ,  $\text{HCO}_3^-$ , etc.). In order to specify the properties of water, it is necessary to determine the following parameters: pH, color (due to mineral salts, colloidal organic matter), turbidity

(sands, etc.), temperature, total mineralization (or dry residue), total hardness, alkaline strength, total alkalinity, etc. and dissolved gases. For corrosion to occur an oxidizing agent must be present and, in most natural waters, this is usually dissolved oxygen. However, it is important to remember that other species (e.g.,  $\text{Cu}^{2+}$ , sulfur, etc.) can also act as oxidizers.

#### 3.02.4.2.2 Aggressiveness and corrosiveness of water

The aggressiveness of water is usually dependent on its acidity and this, in turn, depends on the presence of dissolved  $\text{CO}_2$ , which is in equilibrium with carbonate species and carbonic acid. Additional equilibria also exist with dissolved calcium and magnesium ions that result in these being undersaturated or supersaturated with respect to precipitation as the corresponding carbonate. For a given water chemistry, sufficient dissolved carbon dioxide must be present in order to prevent this precipitation. There is, therefore, a saturation equilibrium and pH for dissolved  $\text{CaCO}_3$ .<sup>23–26</sup> The governing equilibrium equations for this process are:

These equilibria control whether protective calcium carbonate films either deposit or not on the interior of the water pipe. In the absence of the carbonate film, the corrosion rate of the iron is increased and the water is therefore said to be aggressive (**Figure 11**).

Tillmans' formula gives the pH as a function of the free  $\text{CO}_2$  and the alkalinity in  $\text{CaCO}_3$  where the free  $\text{CO}_2$  and  $(\text{CaCO}_3)$  have units of  $\text{mg l}^{-1}$  (i.e., ppm)<sup>27</sup>:

$$\text{pH} = 7 - \log \frac{3 \times \text{freeCO}_2}{0.61 \times (\text{CaCO}_3)}$$

**Figure 10** Results of a 7.5-year exposure test program on 150 × 100-mm panels at Kure Beach, N.C. Reproduced from Mannweiler, G. B. *Proc. Am. Soc. Test. Mater.* **1972**, 72, 42.

**Table 8** Corrosion rates after exposure for 7.5 years at Kure beach

Alloy	Corrosion rate (mm year <sup>-1</sup> )
0.2% Cu steel	0.020
Cast iron	0.010
Types 1 and 2 Ni-Resist	<0.003
Type 4 Ni-Resist	<0.003

Langelier's formula can be used to determine an index of aggressiveness, Langelier saturation index (LSI):

$$\text{LSI} = \text{pH} - \text{pH}_s$$

where  $\text{pH}_s$  is the pH of saturation of  $\text{CaCO}_3$

- If LSI is negative, the water is aggressive;
- if LSI is zero, the water is inert;
- if LSI is positive, the water is scale-forming, calcareous.

To limit attack, the corrosion rate of the iron must be less than the rate of formation of the protective carbonate containing the deposit. Various conditions must then be satisfied: the water must not contain excessive  $\text{CO}_2$  and the pH must be above 7.4 for normally mineralized water, or 7.6 for soft water. To know whether water is calcareous or aggressive, it is also possible,<sup>28</sup> to refer to **Figure 12** and identify the water condition with respect to the carbonic acid equilibrium.

The corrosiveness of water in this context may be related to the presence of electrolytes in solution, mainly chlorides and sulfates, as measured by the conductivity. The point at which it starts to become significantly corrosive is also dependent on the dissolved oxygen concentration and other factors.

However, **Table 9** provides general indications for the limits of  $\text{Cl}^-$  ions and  $\text{SO}_4^{2-}$  ions before water can be thought of being significantly aggressive.

Importantly, it must be realized that the action of water on a pipe is also a dynamic phenomenon in which the flow velocity of water, its content of dissolved gases (e.g.,  $\text{O}_2$ ), matter in suspension, and microbiological phenomena must be taken into account. Potable water can dissolve  $\sim 40 \text{ cm}^3$  of air per liter of water, of which  $6 \text{ cm}^3$  is oxygen and  $14 \text{ cm}^3$  is nitrogen. A dissolved oxygen content of less than this value is a sign of the presence of organic matter; the presence of hydrogen sulfide suggests active sulfate reducing bacteria.

### 3.02.4.2.3 Influence of dissolved oxygen

Dissolved oxygen plays a critical role on the corrosion of iron (as it does for most metals). It is usually the primary cathodic reactant (oxidant) and its rate of influx at the metal surface influences the corrosion rate. Thus, the corrosion rates of many systems are controlled by the mass transport of dissolved oxygen to the reacting surface and this, in turn, is controlled by the concentration of dissolved oxygen, the fluid flow rate and the presence or absence of films (such as calcium carbonate or rust) on the surface. In the case of ferrous alloys (including iron and cast irons), the corrosion products (iron oxides) on the surface are more or less hydrated and have different crystallographic structures. Rust, therefore, often has several constituents, in particular: goethite ( $\alpha\text{-FeOOH}$ ); lepidocrocite ( $\gamma\text{-FeOOH}$ ) and magnetite ( $\text{Fe}_3\text{O}_4$ ).

In the absence of dissolved oxygen, the corrosion rate of iron and of low-alloy cast iron is low. However, once the  $\text{O}_2$  concentration increases, corrosion increases. In general, any process that modifies the

200 ppm	400 ppm	30
300 ppm	420 ppm	CEFRACOR

mass transport of oxygen to the metal surface for reaction (including the concentration of oxygen and the rate of agitation of the fluid) influences the corrosion rate. Note, however, that the presence of dissolved  $\text{O}_2$  can assist in the passivation of some alloy

cast irons. Moreover, the absence of oxygen, at least locally, can prevent the formation of a protective deposit or favor corrosion by differential aeration or crevice corrosion. This is the case, for example, of corrosion under deposits of scale, under joints, and on the plates of tube exchangers.

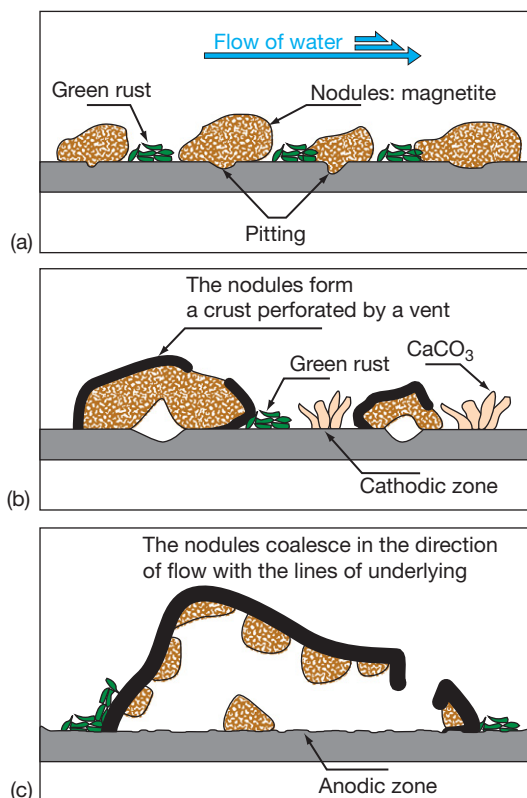

One interesting study has shown the influence of the concentration of dissolved oxygen on the mechanisms responsible for the corrosion of cast iron in water at  $50^\circ\text{C}$ .<sup>31</sup> The results of this study can be summed up using Figures 13 and 14.

#### 3.02.4.2.4 Corrosion of cast iron in natural water

Generally, cast irons provide excellent service in water following the formation of a protective layer on the inside wall of the pipe (layer of carbonate, most often). However, water that contains carbon dioxide in solution, acid effluents, chlorides, etc., is significantly more corrosive.

The presence of alloying elements of moderate composition has no great influence on the corrosion rate of cast irons in water. For example, a German study<sup>32</sup> has shown that the addition of 0–3% nickel does not improve the corrosion resistance of cast iron in artificial seawater, cooling water, or soft water. However, according to the same authors, the corrosion rate can be reduced by 50% in water containing dissolved  $\text{H}_2\text{S}$ , but the corrosion is still so high that this is not considered a cost-effective solution. In practice, the conditions that the castings are exposed to influences the corrosion rates. Typical corrosion rates for graphitic and 18% nickel (austenitic) cast iron in various environments are given in Table 10.

The use of Ni-Resist cast iron is recommended in the following cases: borehole water, fresh water with a brackish tendency ( $\text{pH} = 7.6$ ), water at  $80^\circ\text{C}$

**Figure 13** Steps in the development of the layer of oxides that forms on lamellar graphite unalloyed cast iron immersed in water at 50 °C containing 0.44 ppm oxygen: (a) from 3 to 7 h (b) after 10 h (c) from 16 to 40 h. Reproduced with permission from Smith, D. C.; MacEnaney, B. *Corros. Sci.* **1979**, *19*, 379–394.

accompanied by ammonia vapors, and sulfite-rich water (pH = 3.5; e.g., from paper mills). On the other hand, low- or unalloyed cast irons can provide an adequate service life in the presence of more or less aerated water containing a large number of organic substances (low-alloy cast iron: 1.5% Ni + 0.5% Cr, for example). Small levels of copper and chromium also reduce the corrosion of lamellar graphite cast irons.

In certain cases, inhibitors may be used to protect cast irons against corrosion by water assuring that the materials are in a closed circulation system. The use of alkaline anodic inhibitors, such as 1% sodium silicate and 0.5% sodium nitrite, is effective. A mixture of phosphonocarboxylic acid and sodium nitrite also appears to be effective against the corrosion of cast irons by neutral solutions.<sup>22</sup> This results in the formation of a finer and more protective passive film than is formed in the presence of nitrite alone. A ranking of the inhibitors commonly used for closed

**Figure 14** The same as **Figure 13**, but in water at 50 °C containing 3 ppm oxygen: (a) after 10 min (b) after 3 h (c) after 6 h (d) after 27 h. Reproduced with permission from Smith, D. C.; MacEnaney, B. *Corros. Sci.* **1979**, *19*, 379–394.

cooling circuits has been proposed for cast irons although benzoates, known to be effective with steel, tend to aggravate the corrosion of cast irons:

- good protection: nitrites, phosphates;
- average protection: silicates, tannins;
- positive or negative effect according to conditions: borates.

Water containing sulfates generally has an electrochemical corrosive action on metals when the iron content exceeds 400–500 mg l<sup>-1</sup>. Note also the possible appearance of pitting corrosion, by differential aeration, under scales containing sulfates.<sup>33</sup> To forestall corrosion of cooling circuits, we must ensure that the sum (Cl<sup>-</sup> + SO<sub>4</sub><sup>2-</sup>) is less than 250 mg l<sup>-1</sup>;

corrosion becomes likelier when this sum exceeds 500 mg l<sup>-1</sup>.

In 2002, Indian researchers,<sup>34</sup> by means of electrochemical tests (measurements of Tafel slopes and of polarization resistance, for example), established a ranking for the aggressiveness of saline solutions at 28 °C on a cast iron. The concentrations tested were dilute (from a few ppm to a few hundred ppm), and likely to be encountered in drinking water. KCl and NaCl would seem to be more corrosive than MnSO<sub>4</sub>, Pb(NO<sub>3</sub>)<sub>2</sub>, KI, and KBr. The variation of the corrosion rates over time (up to 360 h) were also tracked: the results are given in Table 11.

**Table 10** Corrosion rates of unalloyed and austenitic cast irons in various waters

Types of water	Corrosion rate (mm year) <sup>-1</sup>	
	Unalloyed Cast iron	Austenitic Cast iron
Distilled water	0.25	0.015
CO <sub>2</sub> purifier water	4.06	3.05

Data taken from Mehra and Soni.<sup>34</sup>

In early 2000, Japanese researchers<sup>35</sup> studied the effect of pH on the corrosion behavior of underground SG cast iron pipes immersed in simulated underground water (using polarization curves and immersion tests). The intended application was corrosion resistance in clay-rich marine mud. The study highlighted the effects of an intensive selective dissolution of the ferrite of the pearlite where phosphorus and sulfur seem to have segregated; spheroidal graphite and cementite favor the evolution of hydrogen. The schematic diagrams in Figure 15, sum up the mechanisms.

### 3.02.4.2.5 Galvanic corrosion of cast iron in natural water

Scandinavian authors<sup>36</sup> have reported interesting data on the corrosion by galvanic coupling of unalloyed cast iron with various alloys in town water at 25 °C and 75 °C (temperatures encountered in household sanitary installations); Table 12 groups these data.

These data show that the unalloyed cast iron is anodic, compared to the metals and alloys studied; only carbon steel and zinc are anodic with respect to

**Figure 15** Selective dissolution of the ferrite of the pearlite where phosphorus and sulfur have segregated. Reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

**Table 12** Corrosion potentials and galvanic currents for the listed materials coupled to LG iron

Alloys coupled to the cast iron	Town water at 25°C		Town water at 75°C	
	Current density ( $\mu\text{A cm}^{-2}$ )	Corrosion potential (mV/SHE)	Current density ( $\mu\text{A cm}^{-2}$ )	Corrosion potential (mV/SHE)

cast iron. On the subject of galvanic corrosion, reference to Bryant<sup>37</sup> will also be useful. Another type of 'galvanic' corrosion can occur on the same section of iron due to thermal-galvanic effects. Thus, the coexistence, in a single pipe, of hot zones and cold zones can create a chemical heterogeneity at the cast iron surface which leads to clearly separated anodic and cathodic regions. In this way a temperature difference of 20 °C can lead to a potential difference of 55 mV.<sup>38</sup>

Swedish work on the effects of galvanic coupling between SG cast iron and copper in water, published in 2005,<sup>39</sup> has shown that deaeration of water can diminish the galvanic corrosion of the cast iron, with the corrosion rate becoming equal to that observed in the absence of copper. The corrosion products formed on the surface of the cast iron under these conditions of deaeration have the appearance of a black film that consists of magnetite. However, if the temperature is raised from 30 °C to 50 °C, the galvanic corrosion current is multiplied by 10, even under conditions of deaeration.

#### 3.02.4.2.6 Inhibition of corrosion in water

Traditionally, a standard range of species can be used to inhibit the corrosion of cast irons. Chromates were previously used as anodic passivating inhibitors, however, this is no longer permitted due to the toxicity of hexavalent chromium. Alternative anodic inhibitors include nitrites, molybdates and phosphates. Film-forming organic inhibitors such as octadecylamine can be used commonly in boilers and refrigeration installations, etc. Tannins are often used as an

internal treatment for low-pressure steam boilers. Indian work in 2004, comparing the actions of different inhibitors of corrosion of cast irons in water,<sup>40</sup> showed that, among the products tested (molybdate, hydrogen phosphate, and nitrite), it is the molybdate ion that is the most effective. For potable water systems below 60 °C, sodium hexametaphosphate combines inhibition of scaling (at lower concentrations) and corrosion (at somewhat higher concentrations). It is one of the few chemicals that are permitted for use as a corrosion inhibitor for potable (drinking) water.

#### 3.02.4.3 Corrosion in Steam

Ordinary cast irons are acceptable up to a few bar wet steam pressure (120–130 °C) while silicon cast irons (>15%) resist steam up to 300 °C. Under more severe conditions of service, austenitic cast irons are recommended. For example, in saturated steam at 170 °C (8 bar pressure) the loss of thickness for Ni20Cr3 (LG1 grade) is 0.02 mm year<sup>-1</sup>. For steam at higher temperatures (up to 500 °C), castings must undergo a stabilization heat treatment (annealing at 760 °C for 4 h followed by cooling in the furnace down to ~500 °C). Generally, the high temperature corrosion of cast iron in steam is similar to steel. Thus, in the presence of superheated steam, from 450 °C to 600 °C, after 0.5–3 h of exposure, a film of magnetite (Fe<sub>3</sub>O<sub>4</sub>) forms on unalloyed cast irons, reinforced by wustite (FeO) if the temperature exceeds 575 °C. It is important to note that the relatively poor mechanical properties of cast iron compared with steel, constrain the application of cast irons to those at lower pressures.

### 3.02.4.4 Corrosion in Seawater

Evans,<sup>41</sup> in 1928, cites Hadfield, who describes various cases of cast iron foundations left in seawater for 25–50 years: they become extremely soft, to the point of consisting primarily of graphite and of the corrosion product. Evans points out that this ‘graphitic softening’ with no change of outward appearance is often found in cast iron objects that have remained immersed in the sea for a long time. He also recalls that cast iron objects from shipwrecks, found later, often seem at first glance not to have been affected, but are in fact constituted essentially of soft ferrous hydroxide held together by graphite lamellae; this ferrous hydroxide is subsequently oxidized when the objects are exposed to open air and akaganite ( $\beta$ -FeOOH).

Research has shown that the corrosion rate of cast iron in sodium chloride passes through a maximum at 3–3.5% NaCl,<sup>42</sup> a concentration that corresponds more or less to the composition of seawater (Figure 16). In short, seawater is an aggressive medium for cast irons, but their behavior is strongly influenced by the location and its specific conditions.

Tables 13 and 14 provide some examples. A corrosion rate of 50–100  $\mu\text{m year}^{-1}$  is often given for unalloyed cast irons in seawater. All tests were conducted on small plates taken from pipes, machined and ground to eliminate the protective action of the casting skin. They clearly show that the corrosion of cast iron in seawater is not excessive (2–3 times that in distilled water) and that there is no significant difference between lamellar graphite cast iron and spheroidal graphite cast iron.

**Figure 16** Effect of the concentration of NaCl on the corrosion rate of iron in aerated solutions at ambient temperature. Reproduced with permission from ASM. Corrosion of cast irons. Metals Handbook, Corrosion, 1987, Vol. 13; pp 566–572.

Alloying additions of nickel or chromium greatly reduce corrosion. As shown in Figure 17, austenitic cast irons stand up much better than other cast irons to seawater, water contaminated by certain industrial pollutants, and water rich in  $\text{CO}_2$ . For the desalination of seawater, austenitic nickel cast iron is specified for many pumps and valves operating in the feed seawater and in the brine. Similarly, many cooling water pumps made up of this type of cast iron have been installed in conventional power stations, refineries, and steel mills.

Even though seawater is an aggressive medium for cast irons, a unalloyed cast iron can provide satisfactory service if the seawater is still and not polluted. Japanese authors have shown that the resistance of cast irons to seawater corrosion improves as the carbon content decreases and the silicon content increases. In addition, the nature of the matrix seems to have a large influence: white cast irons having an extensive carbide structure are the most resistant, followed, in order of decreasing corrosion resistance, by ferritic, ferrite–pearlitic, and finally pearlitic gray cast irons. Low contents of chromium improve the resistance of lamellar graphite cast iron to corrosion by seawater. Small additions of molybdenum, vanadium, and titanium increase corrosion resistance by refining the graphite and the matrix.

In flowing seawater, the commonest type of exposure, the corrosion rate varies with the velocity of water and increases rapidly as the velocity increases because more oxygen is available. It is also stated that the corrosion rate can be up to 15–25 times as great as in stagnant seawater; but it would seem that at still higher velocities, the level of corrosion can be decreased by the formation of a protective oxide deposit. Some authors<sup>43,44</sup> recommend using austenitic nickel cast irons for cases of corrosion–erosion in seawater, since these cast irons have an excellent resistance to such attack. The resistance of high-silicon cast irons in seawater has also been studied. However, it turns out that these are sensitive to pitting corrosion in stagnant seawater (and at low flow rates). Such pitting is initiated at the matrix/graphite lamellae and matrix/interdendritic carbide interfaces. Otherwise, in flowing water, their resistance to corrosion–erosion is excellent (Table 15).

The water temperature also plays a more or less marked role according to the grade of cast iron, as shown in Figure 18. Additionally, some British studies<sup>45</sup> have shown that there are practically no differences in corrosion behavior among the various unalloyed gray cast irons (lamellar or nodular

**Table 13** Corrosion rates of gray cast irons in various sea water environments

graphite, ferritic or pearlitic). According to the same authors, resistance of 'Ni-Resist' cast irons to seawater is better (2–3 times greater than that of unalloyed cast irons) even though it is the high-silicon and high-chromium grades that are generally thought to be the most resistant to corrosion in this medium.

This work also demonstrates the value of protection by coatings: examination of castings that had been metallized (by thermal spraying with aluminum) shows that the loss of mass is five times lower than for unprotected castings and significantly less than for austenitic cast irons. In the case of salt water mists at 100 °C, alloyed cast irons are generally recommended.

There is an interesting study<sup>46</sup> of the influence of ferrous sulfate (a corrosion inhibitor for copper alloy condenser tubes used in seawater) on the corrosion of

an austenitic cast iron of the Ni20Cr2 LGI type in seawater. It showed that the presence of  $\text{Fe}^{2+}$  ions could make seawater more corrosive if the concentration of these ions was not too high (less than or equal to 100 ppm). On the other hand, contents 10–25 times as high would tend to diminish the corrosion rates.

Dutch work<sup>47</sup> has shown that the corrosion products formed on spheroidal graphite cast iron immersed in water differed substantially according to whether the iron is exposed under static or flowing conditions. For example, it was shown that these corrosion products consisted of  $\alpha$ -FeOOH in a spongy form under static condition and of a hard mixture of  $\gamma$ - and  $\alpha$ -FeOOH under dynamic condition.

The austenitic irons have also been shown to exhibit better corrosion resistance than the ferritic irons in seawater. Tests over long periods of time have shown

that Ni-Resist irons of Types 1, 2, and 3 corrode at rates of 0.020–0.058 mm year<sup>-1</sup> in relatively quiet seawater. Under similar conditions low alloy cast irons have shown corrosion rates ranging from 0.066 to 0.53 mm year<sup>-1</sup>.<sup>22</sup> The Ni-Resist irons maintain this superiority over a wide variety of conditions (Figures 17 and 18), both in stationary and flowing seawater. In a test lasting 740 days in seawater moving at 1.5 m s<sup>-1</sup>, low-alloy cast iron showed a corrosion rate of 1.3 mm year<sup>-1</sup> compared to 0.050 mm year<sup>-1</sup> for Type 2 Ni-Resist. In tests carried out at controlled temperature at a higher

**Figure 17** Comparison of the corrosion rates of a unalloyed cast iron, a 'Ni-Resist' cast iron, and a bronze in seawater. Reproduced with permission from Berenson, J.; Wranglen, G. *Corros. Sci.* **1980**, *20*, 937–941.

velocity of 8 m s<sup>-1</sup> (Table 16), the Ni-Resist irons again showed better properties than low-alloy cast irons or mild steel.

### 3.02.4.5 Soil Corrosion

Since buried pipes for water, sewage, and gas are a major use of cast iron, the corrosion of buried iron structures needs special consideration in any study of the corrosion properties of cast iron. With gray iron pipes, leakage usually arises because the pipe fractures as a result of soil stresses or top-loads that exceed the hoop strength of the pipe. With ductile iron pipes, leakage is usually through small corrosion pits. For this reason gray iron pipes are susceptible to both uniform and pitting corrosion while ductile iron pipes are only seriously affected by pitting. A characteristic of corrosion on buried ferrous metals is that the attack is mostly in the form of pitting, especially with the cast irons. This causes a problem in measuring the extent of corrosion in burial trials. Usually both the weight loss, measuring the average loss of section, and the deepest pit, measuring the maximum loss of section, are reported. For assessing the severity of the attack on buried pipes, the second parameter is clearly the most important.

The rate of attack on buried iron depends on the corrosivity of the soil in question. A good guide, which is still valid, is the work carried out by the National Bureau of Standards in the United States between 1922 and 1955.<sup>48</sup> In this very detailed and extensive study, the chemical characteristics of more than 100 soils drawn from all over the United States were examined and compared in relation to the

corrosion behavior of small steel and iron specimens that had been buried in them for up to  $\sim 17$  years. Detailed study of the published results suggests, however, that the only parameter to give any useful correlation with the severity of the corrosion is the electrical resistivity of the soil. Even this is only valid up to  $\sim 2000$  ohm cm with a correlation coefficient of  $\sim -0.5$ .<sup>49</sup> Currently, electrical resistivity is the factor used for dividing soils into corrosivity classes (Table 17).

Although resistivity surveys can decide which soils along a projected pipeline are probably aggressive to buried ferrous metals and which are not, it has been found that when unprotected pipes fail in service the local soil resistivity does not correlate to any significant extent with the corrosion rate at the pitted site. Indeed, Stokes<sup>50</sup> showed from a survey of statistics of ductile iron pipe failures in the United Kingdom, that the most likely pitting rate for an aggressive soil is  $\sim 1$  mm year<sup>-1</sup> with a range of  $\sim 0.3$ – $3$  mm year<sup>-1</sup>. Since the soil electrolyte is likely to be a dilute salt solution of low dissolved oxygen content and pH  $\sim 8.5$ , a consistent corrosion rate seems logical. Collins<sup>51</sup> has suggested that the tendency for low resistivity soils to be aggressive is due to the fact that for the most part they are poor in draining, and poorly aerated heavy clays are thus more liable to create differential concentration cells on the pipe surface than free-flowing soils such as sands. He argues that, as the soil resistivity falls, the probability of serious pitting increases but the pitting rate remains substantially constant. This would explain the poor correlation between the chemical parameters of the soil and its corrosivity. It also suggests that the physical characteristics of the soil should be better indicators of its corrosivity.

The results of tests on bare cast iron in soils that are relatively homogeneous on the scale of the size of the samples cannot be directly extrapolated to actual coated pipes; the latter, because of their length, will encounter a succession of soils (geological cells) that differ in their nature, their moisture content, their aeration – soils are sometimes made heterogeneous by borrowed materials or by differences of compaction. For example, in the case of a pipe passing in turn through a porous soil permeable to air, then a clay layer through which oxygen can pass only with great difficulty, a differential aeration cell may form, which results in the corrosion of the part of the pipe in the clay soil (which becomes the anode as it is in a region of oxygen restriction) while the part in the porous soil is only slightly corroded (since it is in a region with more easy oxygen access and is, hence, cathodic).<sup>52</sup> Additionally, corrosion of cast iron pipes in soils may also be affected by stray or induced currents: for example, from DC traction systems, induced AC current or from other cathodic protection systems.<sup>53,54</sup> Many of these conditions, which are difficult to circumvent, are likely to result in the formation of macrocells leading to a localized corrosion (pitting) that can be dangerous when the soil is highly corrosive.<sup>55</sup> Coupling with copper used for

water distribution pipes can also result in the functioning of macrocells.<sup>56</sup>

In early 2000, Japanese researchers<sup>57</sup> studied more particularly the corrosion resistance of SG cast iron pipes in clay marine muds. In 2003, Kubota (Japan) patented a spheroidal graphite cast iron having

improved corrosion resistance and high mechanical strength, for the production of pipes for underground applications.<sup>58</sup> Its composition is reported as: 3–4% C, 1–4% Si,  $<0.6\%$  Mn, 0.02–0.08% Mg, 0.05–0.5% Co,  $<1.5\%$  Ni, 0.2–0.8% Cr, and/or Cu.

It should be noted that it is extremely difficult to predict service lives of buried pipelines from the results of controlled trials with small specimens, whether in the laboratory or in the field. For example a study on the comparative corrosion resistances of ductile and gray iron pipes between 1964 and 1973<sup>59,60</sup> indicated a mean pitting rate of  $0.35 \text{ mm year}^{-1}$  for uncoated ductile iron pipe exposed in a typical heavy Essex clay of  $500\text{--}900 \Omega \text{ cm}$  resistivity for 9 years. This contradicts the rate of  $1 \text{ mm year}^{-1}$  normally found on a corroded service pipe from such a soil. The discrepancy appears to be due to the use of specimens that were only a third of a pipe length each and were buried separately. It may reflect the contribution of the total surface area of the pipe as a cathode to the corrosion current at the anodic area of the pitting site.

### 3.02.4.6 Methods of Protection

Experience and knowledge of the corrosion caused by local geological differences (macrocells) in the soil have led to the development not only of methods of evaluation of the corrosiveness of soils on a pipe alignment (e.g., by soil resistance survey), but also of methods of protection capable of disrupting the

macrocells. These methods include: ensuring that electrical continuity along the pipe is broken by use of insulating joints (also limiting stray currents), using active coatings that are self-healing (e.g., zinc), use of an inert backfill<sup>61</sup> and, for difficult cases, placing a flexible polyethylene sleeve around the pipe when it is laid to prevent direct contact with the local heterogeneities of the soil.

Note that cathodic protection is also an excellent remedy for corrosion of cast iron by soils (although it is most often applied to steel pipes).<sup>62,63</sup> For steels, cathodic protection is often combined with a protective organic coating<sup>64,65</sup>; this is rarely done in the case of cast irons. However, cathodic protection of the town water supply network of Scarborough, United Kingdom has been undertaken.<sup>62</sup> This network, made up primarily of ductile cast iron and lamellar graphite cast iron pipes, is protected by magnesium sacrificial anodes to overcome the problems due to the corrosiveness of soils (resistivity from 1000 to 3000  $\Omega$  cm), which is due partly to the use of deicing salts, and also to galvanic coupling with the copper used in distribution pipes. It must be borne in mind that the cathodic protection of a structure may also generate stray currents in the soil. It may then create, in an adjacent metallic structure, zones of current input and zones of current output at which corrosion will occur. In practice, even though there are many networks of cast iron pipes that coexist in the soil with networks of steel pipes with cathodic protection, there are very few cases of corrosion ascribable to the influence of cathodic protection, because a few simple rules<sup>66</sup> can be applied to solve most of the problems.

### 3.02.5 Corrosion in Industrial Environments

In general, unalloyed gray or white cast irons possess no resistance to dilute mineral acids. In very dilute acids, the presence of air, or other oxidizing agents such as ferric salts, appreciably increases the corrosion rate. If corrosion rates are to be held below 0.25 mm year<sup>-1</sup> in moderately aerated solutions, it is unwise to exceed a total acid concentration of 0.001 M (i.e., pH < 3), irrespective of the acid concerned.

#### 3.02.5.1 Sulfuric Acid

The use of unalloyed cast irons is generally impossible in the presence of dilute sulfuric acid since

the corrosion rates are very high (several millimeters a year).<sup>67</sup> By contrast, the same acid (sulfuric) in the concentrated state barely attacks unalloyed cast irons, even at high temperature. This is due to an iron sulfate salt film that forms at concentrations above  $\sim 70\%$  such that corrosion rates do not exceed 0.13 mm year<sup>-1</sup> at 20 °C.<sup>67,68</sup> In practice, thanks to this passivation effect, lamellar graphite cast irons, in the past, and spheroidal graphite cast irons, today, are used in coolers for concentrated sulfuric acid.

As for alloy cast irons, austenitic nickel grade can provide good corrosion resistance up to 20% sulfuric acid<sup>67</sup>; above this value, high-silicon cast irons must be used. For example, pumps used in the production of sulfuric acid are, in fact, often made of high-silicon cast irons. **Figure 19** shows the behavior of several cast irons under different conditions of service (temperature, concentration).<sup>68</sup> It can be seen that the resistance of these alloys to concentrated sulfuric acid is excellent up to its boiling temperature. Note that it is dangerous to use cast irons with oleum (concentrated sulfuric acid enriched with SO<sub>3</sub>) because of the risk of oxidation of the silicon they contain.

The austenitic irons can be used in handling very dilute solutions of sulfuric acid at ambient or moderately elevated temperatures under conditions corrosive to ordinary cast iron and carbon steel. Austenitic irons have also given satisfactory service in handling concentrated sulfuric acids, but although they show low corrosion rates in such environments they are not markedly superior to the unalloyed cast irons. Type 1 Ni-Resist and the high silicon grades AUS104 and AUS204 are the types most generally used in sulfuric acid environments. The iso-corrosion curves of an austenitic lamellar graphite cast iron containing 15% Ni, 6% Cu, and 2% Cr in sulfuric acid are given in **Figure 20**.

High-chromium irons have no useful resistance to sulfuric acid of more than 10% concentration at any temperature. At temperatures above 20 °C corrosion rates in excess of 1.27 mm year<sup>-1</sup> are probable even for acid of less than 10% concentration. The addition of 2% molybdenum increases the resistance to this acid at very low and very high concentrations (**Figure 21**).

Probably, the most useful characteristic of the high-silicon irons is their ability to withstand sulfuric acid at all temperatures and concentrations. The maximum rate of corrosion which can develop has been reported to be 0.482 mm year<sup>-1</sup> in 30% sulfuric acid at boiling point,<sup>3</sup> and this falls to a minimum rate of 0.025 mm

**Figure 21** Resistance of high-chromium iron containing 2% molybdenum to sulfuric acid solutions.

**Figure 23** Influence of Si content on the corrodibility of cast irons in  $\text{H}_2\text{SO}_4$  (5–30–50%).

**Figure 22** Variation of corrosion rate with concentration of boiling sulfuric acid (Duriron Co. data).

year<sup>-1</sup> when the acid concentration exceeds 60% and the temperature is at boiling point (Figure 22).

In order to achieve optimum performance over the widest possible acid concentration range, it is essential to ensure that the alloy content of silicon is optimal. The corrosion rates of silicon iron are illustrated in Figure 23, which shows the influence of the silicon contents from 13.8% to 15.6%, on the resistance to corrosion by boiling sulfuric acid at different concentrations. From this data, it is clear that silicon contents in excess of 15% provide the best performance. Figure 24 illustrates an iso-corrosion chart for 15% silicon iron in sulfuric acid.

**Figure 24** Iso-corrosion curves in  $\text{H}_2\text{SO}_4$  of cast iron containing 15% Si.

### 3.02.5.2 Hydrochloric Acid

This commonly used acid attacks unalloyed cast irons very strongly, even in a dilute condition. High-chromium cast irons are only slightly better than unalloyed cast irons; the dissolution of these cast irons leaves a residue having a graphitic appearance and consisting of carbides.<sup>69</sup> Austenitic nickel cast irons are also attacked, especially by the cold concentrated acid and by boiling 20% acid. Attempts made to produce an alloy more resistant to hydrochloric acid have resulted in alloys containing 17–18% silicon or 14.5% silicon and chromium plus 3% molybdenum and both these alloys resist even concentrated hydrochloric acid relatively well. This is due to the protective layer of  $\text{SiO}_2$  that forms on the surface of the material. If the acid is boiling, the attack of such cast irons will be much more intensive and this is illustrated in Figure 25. For example, with a cast iron containing 15% Si and 3% Mo

**Figure 25** Limits of use of silicon irons in HCl for Fe–18Si and Fe–14.5Si alloys.

**Table 18** Corrosion of Type 1 Ni-Resist, cast iron and carbon steel in deaerated HCl at room temperature

Acid concentration (%)	Corrosion rate (mm year <sup>-1</sup> )		
	Ni-Resist	Cast iron	Carbon steel

36.0	9.4	28	30

in the presence of boiling 20% HCl, the loss of mass is  $150 \text{ g m}^{-2} \text{ day}^{-1}$ .<sup>69</sup>

The austenitic irons are superior to ordinary cast iron in their resistance to corrosion in deaerated hydrochloric acid at room temperature (Table 18). However, for practical uses where such factors as velocity, aeration and elevated temperatures have to be considered, the austenitic irons are mostly used in environments where the hydrochloric acid concentration is low, generally less than 1% and preferably below 0.5%. Such environments occur in process streams encountered in the production and handling of chlorinated hydrocarbons, organic chlorides and chlorinated rubbers.

### 3.02.5.3 Nitric Acid

Unalloyed cast irons are not suitable for castings resistant to nitric acid, at any concentration. Nitric acid also attacks high-nickel cast irons at all concentrations, but more specifically in dilute solutions. Only high-silicon and high-chromium cast irons display good resistance to this acid, due to the formation of passive oxide films. However, there may be some corrosion in boiling concentrated solutions. This will, for example, be the case of cast irons containing 29% chromium, the chemical composition of which will be adjusted according to the concentration and temperature of the nitric solutions.<sup>69</sup>

Figure 26 has been derived from data<sup>2</sup> for corrosion by nitric acid solutions of an alloy containing 29% chromium and 0.8% carbon. It is interesting to note that the resistance by this alloy in these solutions is roughly complementary to that of the high-silicon irons, the high-chromium iron being more suitable for dilute solutions and the high-silicon iron for concentrated solutions.

Nitric acid is also withstood by high-silicon iron. The concentrated acid is believed to reinforce the silica film by the formation of a passive iron oxide film, and this assumption is supported by the fact that the highest rates of attack are associated with hot dilute solutions. The iso-corrosion rate data for 14% silicon iron in nitric acid is shown in Figure 27.

### 3.02.5.4 Phosphoric Acid

Phosphoric acid attacks unalloyed cast irons at all concentrations. Austenitic cast irons are satisfactory when used at ambient temperature in solutions having concentrations less than or equal to 30%; above this threshold, the attack is rapid. High-chromium cast irons are suitable in most cases. The corrosion rates

**Figure 26** Resistance of high-chromium iron to nitric acid solution.

**Figure 27** Corrosion resistance in  $\text{HNO}_3$  of a cast iron containing 14% Si).

are  $\sim 0.12 \text{ mm year}^{-1}$  up to a concentration of 60%, at all temperatures up to boiling.<sup>69</sup> High-silicon cast irons best resist this acid, at all concentrations and almost all temperatures (see **Figure 28**). Note that most crude phosphoric acid contains appreciable amounts of fluoride which can lead to excessive corrosion rates.

The results published in the literature suggest that solutions of phosphoric acid at all concentrations and temperatures are not corrosive to high-silicon irons. Kosting and Heins<sup>70</sup> quote long-term results given by the Duriron Co, together with figures obtained in their own tests of 24 h duration (**Table 19**).

**Figure 28** Resistance to corrosion by phosphoric acid of a cast iron containing 14.5% silicon as a function of concentration and temperature. Reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

### 3.02.5.5 Other Mineral Acids

Most cast irons are resistant to chromic acid at all concentrations due to passivation of the material. However, 15–17% silicon irons are recommended at higher temperatures up to  $150^\circ\text{C}$ ; the corrosion of these cast irons is less than  $0.1 \text{ mm year}^{-1}$ . In dry hydro-halide acids (i.e.,  $\text{HBr}$ , etc.) unalloyed irons suffice, however, in wet acids high silicon iron is essential, preferably containing molybdenum. Hydrogen cyanide is generally noncorrosive except at higher temperatures in the gas phase if the humidity is sufficiently high.<sup>71</sup>

### 3.02.5.6 Organic Acids

The short-chain organic carboxylic acids attack unalloyed cast irons, especially in dilute solutions. Thus, unalloyed cast irons should not be used in formic or acetic acids, however, chromium cast irons are acceptable for both, with nickel austenitic iron acceptable for acetic acid. As the chain length of the acid increases, the acidity diminishes and the unalloyed irons may have acceptable corrosion rates. Thus, in palmitic (hexadecanoic) acid unalloyed cast irons should not be used while nickel cast irons are recommended, and in stearic (octadecanoic) acid unalloyed irons may be acceptable at lower concentrations and temperatures.<sup>71</sup>

Therefore, for most organic acids, the corrosion resistance of cast iron is essentially dependent on the strength of the acid. Thus, unalloyed cast irons should not be used in citric, lactic, or oxalic acids ( $3 \text{ mm year}^{-1}$  for unalloyed iron in citric acid) while for white chromium cast irons, the rate of attack is less than  $0.01 \text{ mm year}^{-1}$ .

**Table 19** Corrosion of high-silicon irons by phosphoric acid

25	82–88	0.010	Duriron Co.
	98	0.038	Kosting & Heins
50	98	0.185	Kosting & Heins
87	82–88	0.010	Duriron Co.

**Table 20** Corrosion of Type 1 Ni-Resist and ferritic cast iron in acetic acid at 15 °C

Acid concentration (%)	Corrosion rate (mm year <sup>-1</sup> )	
	Cast iron	Ni-resist
5	17	1.0
10	22	0.5
25	20	0.5
50	16	2.0

The austenitic irons are also useful in some circumstances for handling organic acids such as dilute acetic, formic and oxalic acids, fatty acids and tar acids. They are more resistant to organic acids than unalloyed cast irons, for example, in acetic acid the austenitic irons show corrosion rates 20–40 times lower than the ferritic iron (Table 20).

### 3.02.5.7 Corrosion by Alkalis

Dilute alkali solutions do not corrode cast iron at any temperature, but hot solutions exceeding ~30% concentration will attack it, with an accompanying evolution of hydrogen; this behavior is similar to that of steel. Broadly speaking, if the corrosion rates are to be held below 0.2 mm year<sup>-1</sup> the temperature should not exceed 80 °C; corrosion rates may range as high as 1.25–2.5 mm year<sup>-1</sup> in boiling solutions of more than 50% concentration. Molten caustic soda (650 °C) may attack cast iron initially at rates ~20 mm year<sup>-1</sup>, but this decreases significantly after some exposure. In spite of these high corrosion rates, caustic concentration and fusion pots are made from cast iron, since the material is relatively cheap, and the thick wall necessary for mechanical strength also gives the pot a long life. It is of utmost importance to ensure that concentration and fusion pots are cast in sound metal, as any unsoundness, particularly at the bottom of the pan, will lead to pitting attack and

**Figure 29** Effect of nickel additions to cast iron in reducing corrosion by caustic alkalis.

premature failure. On the other hand, high-silicon cast irons are less resistant to corrosion by alkalis than unalloyed cast irons and this is due to dissolution of the protective silicon oxide film by the alkali. Similarly, ferritic chromium cast irons should not be used in the presence of alkalis.

Austenitic cast irons show particularly good corrosion resistance in alkaline environments, even better than that shown by low alloy cast irons. The resistance to corrosion improves with increasing nickel content (Figure 29), and the irons containing ~30% nickel, such as Type 3 Ni-Resist, show the best resistance. An electrochemical study of the corrodibility of unalloyed SG cast irons in caustic soda has shown that some inhibition can be expected from the addition of thiourea<sup>72</sup>: 36% protection was found with the addition of 10<sup>-3</sup> moles of thiourea per liter of a molar solution of sodium hydroxide at 30 °C.

The addition of 3–5% nickel improves the resistance of both lamellar graphite and spheroidal graphite cast irons to alkali attack and, with increasing nickel content, the corrosion resistance of austenitic

cast irons in these media is much lower than that of non or low-alloy cast irons and alloys containing 30% nickel are the least vulnerable to corrosion by alkalis. For a 50% solution of caustic soda at 50 °C, the use of a Ni-Resist cast iron containing 20–30% nickel and 2–3% chromium is recommended. Figure 30 shows the corrosion rates of austenitic cast irons and of unalloyed cast irons in sodium hydroxide for various temperature–concentration domains.<sup>73</sup>

Test results cited by concerning the resistance of various cast irons in molten anhydrous caustic soda<sup>75</sup> at 510 °C (containing 0.5% NaCl, 0.5% Na<sub>2</sub>CO<sub>3</sub>, and 0.03% Na<sub>2</sub>SO<sub>4</sub>) are shown in Table 21. It can be seen here that the superiority of the austenitic grades

**Figure 30** Corrodibility of austenitic cast irons and unalloyed cast irons in NaOH. Reproduced with permission from Higgins, R. I. *J. Res. Bcira* 1956 6, 165–177.

**Table 21** Corrosion rate and pitting of cast iron in molten, anhydrous NaOH at 510 °C.

Cast iron	Corrosion rate (mm year <sup>-1</sup> )	Pitting depth (mm)

disappears in the case of concentrated caustic soda. This superiority exists only up to concentrations of 70% and temperatures approaching the boiling point. Finally, Table 22 confirms the favorable effect of nickel at lower concentrations<sup>65</sup> (81-day tests).

### 3.02.5.8 Salt Solutions

The corrosion rates of cast irons in salt solutions depend on the salt chemistry. Solutions which are alkaline or neutral in reaction are not generally so corrosive and even brines containing calcium and magnesium chloride can be safely handled by the austenitic irons (Table 23). Those salts which hydrolyze to give an acidic solution (e.g., divalent metal cations such as magnesium) are significantly more corrosive. The corrosion rates of Type 1 Ni-Resist and cast iron given in Table 24 demonstrate that the austenitic iron shows better resistance than the nickel-free cast iron in a wide range of salt solutions.

### 3.02.5.9 Corrosion–Fatigue

Cast iron, exposed under conditions of cyclic stress, is liable to corrosion fatigue. Some data on this effect have been given by Collins and Smith,<sup>75</sup> but a more extensive study has been reported by Palmer<sup>76</sup> who generated stress-cycle (S–N) data using rotating bend at a cycle frequency of 50 Hz and a duration of up to

**Table 22** Corrosion rate of cast iron as a function of nickel content in 30% NaOH solution

10<sup>7</sup> cycles in demineralized water, 3% sodium chloride solution and demineralized water containing various inhibitors. The results for the uninhibited solutions are summarized in Table 25. Palmer found that corrosion fatigue due to water spray could be eliminated or mitigated by some of the inhibitor systems examined, but it was apparently easier to inhibit damage on gray irons than on ductile irons, which could only be inhibited by 0.25% potassium chromate solution. This was due to the inability of the other systems to maintain a continuous passive film on the iron; gray iron is less sensitive to a notch effect in fatigue so that the presence of local sites of attack would be less important to this metal provided that the overall corrosivity of the solution were depressed.

Various studies have also shown that it is possible to protect cast irons against corrosion fatigue by metallization with zinc or aluminum of thickness ~100–200 µm. The life of iron castings exposed to corrosion fatigue conditions in a saline medium is of the same order of magnitude as that of castings subjected to the same mechanical forces in air. Figure 31 clearly illustrates the effect of these coatings.

Another study emphasized, for different types of matrices, the low resistance of SG cast irons to corrosion fatigue in a 3% NaCl solution and the low aggressiveness of lubricating oils.<sup>77,78</sup> The results are shown in Table 26 and Figure 32. Fatigue resistance curves<sup>79</sup> in various media (air, water, salt water) are shown Figure 33. They concern a ferritic SG cast iron tested in rotary bending at 50 Hz. The influence of the aggressiveness of the medium is quite apparent.

An inhibitor consisting of 0.5% NaNO<sub>2</sub> plus 1% NaSiO<sub>4</sub> has been proposed<sup>80</sup> to prevent corrosion

**Table 25** Corrosion fatigue limiting strengths (MPa)

fatigue of pearlitic SG cast irons in water as a replacement for the toxic chromate. Further data, reproduced below (Figure 34), concerning the corrosion fatigue resistance of SG cast irons shows the harmful effect of the marine medium and the value of a metallic coating (zinc or aluminum), which can increase the resistance of the material to that observed in a nonmarine atmosphere.<sup>81</sup>

The fatigue limit under reversing stress and corrosion in hot water at 70 °C in pipes has been studied by Japanese researchers<sup>82</sup> on an as-cast SG cast iron alloyed with copper and molybdenum, and compared to a carbon steel. In the static corrosion test of water containing sulfates and chlorides, the latter was found to be less resistant, and its resistance, unlike that of the former, could not be improved by adding sodium nitrite as an inhibitor. With the cast iron, the corrosive attack practically stopped with inhibitor contents in excess of 6000 ppm. The resistance of this cast iron to corrosion fatigue was also improved; at 260 MPa with 6000 ppm nitrite, it was better than that of the carbon steel.

Japanese researchers considered the question of the corrosion fatigue of ferritic and bainitic spheroidal

**Figure 31** Corrosion fatigue curves of pearlitic SG cast irons: (a) shot-blasted, (b) metallized with Zn, and (c) with Al. Reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

**Table 26** Fatigue resistance of some SG cast irons

Bainite	510	150	500

graphite cast irons (ADI) in water. They found that the fatigue limit of ADI cast irons declined in the course of time, apparently due to a selective dissolution of the acicular ferrite resulting from localized corrosion fatigue. It would seem that ferritic cast irons, in which the selective corrosion of ferrite does not occur, would perform better when exposed to water.

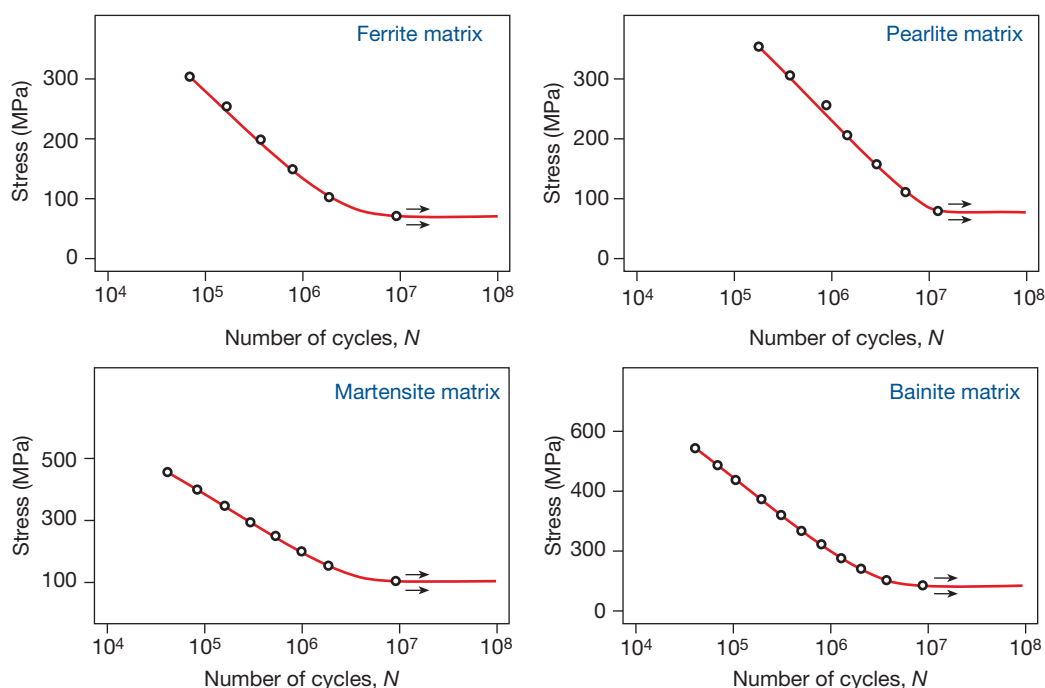

### 3.02.5.10 Stress Corrosion Cracking

In general, it can be said that cast irons are not liable to stress corrosion; however, in some particular media (concentrated sodium hydroxide solution for example),

stress corrosion, cracking of spheroidal graphite cast iron, can be observed.<sup>83</sup> The mechanisms of this type of damage have been studied<sup>84,85</sup> and is similar to steel at the same pH. Lamellar graphite cast irons seem to be less liable to this type of attack; additions of nickel (3–5%) improve the stress corrosion resistance of lamellar and spheroidal graphite cast irons.<sup>86</sup> Tests of the stress corrosion resistance of a ferritic SG cast iron in a medium containing sulfur, (saturated solution of  $H_2S$ )<sup>87</sup> have shown that this type of material is barely liable to this mode of attack – at least not more than a work-hardened carbon steel.

Unalloyed and low-alloyed cast irons are susceptible to varying degrees of stress corrosion cracking in high pH ( $>13$ ), in nitrite solutions, in  $H_2S$ , in acid (where a number of phenomena related to hydrogen occur), etc. These can be mitigated to a greater or lesser extent by alloying, as described elsewhere. Austenitic nickel cast irons are liable to stress corrosion in aerated sodium chloride solution<sup>85</sup> and this can be prevented by use of cathodic protection. Overall stress corrosion can be diminished or even eliminated by reducing the applied stress, by increasing the nickel content, and by reducing the dissolved oxygen content of the medium.

**Figure 32** Corrosion fatigue resistance of SG cast irons having different types of matrices (in 3% NaCl). Reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

**Figure 33** Corrosion fatigue curves of a ferritic SG cast iron in rotary bending (50 Hz).

Unlike most stainless steels, austenitic cast iron, for example the EN-GJSA-XNiCr20-2 type, is not affected by crevice corrosion or by corrosion cracking, even in stagnant solution. Moreover, it provides

cathodic protection to any lower alloy cast steel or iron components. In many cases, however, cracks may occur by stress corrosion cracking in warm seawater, at temperatures above  $\sim 30^\circ\text{C}$ . The tensions that appear are not ascribable to the service loading; rather, they are due to internal stress. For this reason, a careful stress relieving annealing can reliably reduce the risk of stress corrosion cracking.<sup>88,89</sup>

The occurrence of stress corrosion cracking in EN-GJSA-XNiCr20-2 and EN-GJSA-XNiCr30-3 spheroidal graphite cast irons in magnesium chloride solutions containing 5–40%  $\text{MgCl}_2$ , at temperatures ranging from  $20^\circ\text{C}$  to the boiling point, was studied by German authors<sup>89,90</sup> on tensile test pieces and a diagram of the stability as a function of stress in % of yield strength for the two cast iron types is shown in **Figures 35 and 36**.

There exists, for both cast irons and for each temperature, a clear limiting stress below which corrosion cracking no longer occurs. Concerning the influence of the concentration of the solution, it turns out that the life is shortest in a 10% solution of  $\text{MgCl}_2$ . The life is reduced by anodic polarization, while stress corrosion cracking can be blocked by a weak cathodic polarization of 50–100 mV from the resting potential. This implies that the stress

**Figure 34** Effect of Zn and Al coatings on the corrosion fatigue resistance of an SG cast iron in a salt spray (3% NaCl). Reproduced with permission from Forecast Progress in Metal Casting, no. 46, October 1983.

**Figure 35** Diagram of resistance of an ENGJSA-XNiCr20-2 cast iron. Relation between the stress in % of yield strength ( $R_{p0.2}$ ) and the temperature in 5–40% solutions of  $MgCl_2$ . Reproduced with permission from Baumel, A. *Werkstoffe Korros.* **1993**, 44, 107–108.

corrosion cracking of austenitic cast iron is favored by contact with an austenitic stainless steel, even in highly dilute solutions, containing for example 0.1%  $MgCl_2$ , where there is still a sensitivity to stress corrosion cracking at high stresses and temperatures. Also, EN-GJSA-XNiCr-30 cast iron is considerably more resistant than EN-GJSA-XNiCr20-2 cast iron. As the most effective remedy against corrosion cracking under load, a reduction of internal stress by a stress-relieving annealing is recommended. Acceptable residual stress levels of 100 MPa for EN-GJSA-XNiCr20-2 cast iron and 150 MPa for EN-GJSA-XNiCr-30-3 cast iron are allowed.

**Figure 36** Diagram of resistance of an ENGJSA-XNiCr-30 cast iron: relation between the stress in % of yield strength ( $R_{p0.2}$ ) and the temperature in 5–40% solutions of  $MgCl_2$ . Reproduced with permission from Baumel, A. *Werkstoffe Korros.* **1993**, 44, 107–108.

### 3.02.5.11 Organic Compounds

#### 3.02.5.11.1 Alcohol and glycol

Unalloyed cast irons and nickel cast irons can be used for ordinary applications in the presence of hydrocarbons, aldehydes, and amines although some slight attack occurs with the simultaneous presence of

water. Nickel cast irons have complete resistance at all concentrations of these species. On the other hand, alcohol–water mixtures will cause corrosion, the most common application occurring in the use of ethanediol and glycol compounds in automotive antifreeze and coolants. In order to combat this form of corrosion, one or more corrosion inhibitors, such as benzotriazoles and sodium benzoates, are often added, [Table 27](#).<sup>91</sup>

### 3.02.5.11.2 Corrosion by food products

Unalloyed cast irons and nickel cast irons must not be used with wine, vinegar, beer, cider, fruit juices, milk, maltose, and mustard. By contrast, unalloyed cast irons can be used with concentrated beverage, alcohols, and liqueurs. [Table 28](#) provides information about the corrosion resistance of two cast irons in the presence of a number of fruit juices and wine vinegar.

**Table 27** Corrosion rate of unalloyed gray iron in ethanediol–water mixtures in the presence of various inhibitors

Medium	Loss of mass after 50 days testing (mg cm <sup>-2</sup> )
50% Aqueous solution of ethanediol at 70°C (Medium A)	19–21

### 3.02.5.12 Corrosion by Molten Materials

The resistance of cast iron furnace components, especially crucibles, to oxidation at elevated temperatures is important to ensuing dimensional stability and retaining a suitable wall thickness, especially in crucibles. The best material for crucibles from the standpoint of resistance to corrosion is a refractory alloy that can withstand a temperature of the order of 850 °C. According to Polish studies<sup>88,92</sup> a low-alloy chromium cast iron (1.5–3%) best meets this requirement: with such an alloy, the layers of oxides formed on the outside surfaces of the crucibles are relatively thin. The second problem for crucibles containing molten materials is their dissolution. First, a high, but nonuniform, dissolution of the crucible material can lead to the formation of deep local cavities, limiting the life of the crucible. Second, the crucible contents are polluted by iron, which can be a severe problem.

#### 3.02.5.12.1 Corrosion by liquid aluminum or aluminum alloys

Unfortunately, not much is known about the transfer mechanisms of iron from a ferrous crucible into a molten aluminum. However, it is known that the general rate of dissolution of iron into a light alloy increases as the temperature and the silicon content increase.<sup>64</sup> Baths containing magnesium are also highly corrosive, but aluminum alloys containing copper are less so. Among ferrous alloys, cast irons generally resist better than cast steel. According to the Polish work mentioned earlier,<sup>88,92</sup> the best corrosion resistance is found for lamellar graphite cast irons and blackheart malleable cast irons. Some work indicates that high-phosphorus (1.29%) lamellar graphite cast iron displays the best corrosion resistance in liquid aluminum alloys. But that it would be difficult to apply these results in industry, because cast irons having an extensive phosphorus eutectic distribution are not, in other respects, sufficiently resistant to oxidation. As for the influence of chromium, it has been shown that the rate of iron dissolution has a minimum of 2.9% chromium.

Generally, in cast iron crucibles containing molten aluminum, the aluminum diffuses into the crucible surface forming an intermetallic compound (FeAl<sub>3</sub>). This effect reduces the effective difference of aluminum content between the crucible and the liquid alloy, which is one of the drivers for the dissolution process. Some authors<sup>93</sup> have commented that since the FeAl<sub>3</sub> combination contains no carbon, there results an increase of the carbon content on

the perimeter of the ferrous sample, with a clear increase of the pearlite content. This local increase of the pearlite content favors the corrosion resistance of the metal. The same authors have also shown that ferritic white cast irons containing 32% chromium are among the materials that are least resistant to liquid aluminum.

Therefore, it appears that the optimum chemical composition for a cast iron that must resist corrosion by liquid aluminum and silicon alloys is: 3.4–3.5% C, 0.3% P, 2.5–3.0% Cr, 2.0–2.5% Si, 0.1% S, 4.0–5.0% Al, 0.4% Mn and a Polish patent (no. 55.549) was taken out for this grade of cast iron in 1968. In France, a similar cast iron, but containing no aluminum, is generally recommended. However, in practice, the problems of corrosion by liquid aluminum alloys are rarely solved at the metallurgical level; the recommendation most often made is to apply a good dye coating as the only way to ensure a satisfactory life.

### 3.02.5.12.2 Corrosion by liquid zinc and zinc alloys

A phenomenon of gradual dissolution also occurs in the cast iron crucibles used for melting zinc and its alloys. A detailed study at CTIF<sup>94</sup> of the corrosion of ferrous alloys by liquid zinc alloys found that ferrite is the most unfavorable constituent as regards resistance to this type of attack. Pearlite fairs better, even though there is a risk of progression of the corrosion between its lamellae, and a loosening of the latter. This last phenomenon is, however, rather rare: liquid surface tension generally prevents the molten zinc alloy from progressing between the lamellae when the pearlite is fine enough. Hence, it is preferable to avoid coarse structures. Since corrosion advances preferably along the graphite lamellae, it is also best to limit their size as much as is possible; spheroidal graphite once again seems preferable in this respect. As in the case of aluminum, corrosion by liquid zinc is chemical, not electrochemical. Thus, there is no reason to believe that the resistance of an austenitic cast iron of the 'Ni-Resist' type is better than that of a pearlitic cast iron.

### 3.02.5.12.3 Corrosion by other liquid metals

According to various sources, cast iron possesses good resistance ( $<0.025$  mm year<sup>-1</sup>) to dissolution in liquid magnesium, at its melting temperature (651 °C), liquid calcium up to 700 °C, liquid lead up to 500 °C and liquid cadmium at 600 °C. It has limited resistance (0.025–0.25 mm year<sup>-1</sup>) in liquid tin at its

melting point (322 °C), liquid magnesium from 700/800 °C and liquid sodium and potassium at 480 °C. However, cast iron has poor resistance ( $>0.25$  mm year<sup>-1</sup>) in liquid sodium and potassium at 600 °C, liquid tin at 600 °C, and liquid antimony at its melting point (630 °C).

Note that the dissolution of cast iron crucibles used for the melting of metals can sometimes be ascribed to other processes that may accompany the iron dissolution, such as the erosion–corrosion resulting from the flow of the liquid metals, cracking by thermal fatigue or by creep, and high temperature oxidation processes.

### 3.02.5.12.4 Corrosion by liquid sulfur

Table 29<sup>95</sup> indicates the rate of attack in liquid sulfur of a unalloyed lamellar graphite cast iron and of a type EN-GJLA-XNiCuCr15-6-2 austenitic cast iron, as a function of temperature.

It can be seen here that nickel cast irons behave like unalloyed cast irons up to 250–300 °C, and then more poorly at higher temperatures.<sup>96</sup> The addition of silicon (15%), possibly reinforced by an addition of molybdenum (or of chromium or copper), significantly reduces the rates of attack (Table 30).<sup>97</sup>

### 3.02.5.13 Microbially Influenced Corrosion

The role played by microbes in nature is well known. Numerous in the soil and in water, they decompose organic and mineral matter and participate in the

**Table 29** Dissolution rate of cast irons in liquid sulfur

Temperature (°C)	Corrosion rate (mm year <sup>-1</sup> )

grand cycles of carbon, nitrogen, and sulfur. Most of the microorganisms responsible for microbially influenced corrosion can adapt to temperatures between  $-10$  and  $+99^{\circ}\text{C}$ , pH between 0 and 10.5 and concentration of oxygen between 0% and nearly 100%. Many bacterial species produce an extensive range of compounds and species capable of promoting corrosion, including organic acids, sulfuric acid, hydrogen sulfide, etc.

### 3.02.5.13.1 Iron oxidizing bacteria

Iron oxidizing bacteria utilize the transformation of ferrous salts into ferric salts as part of their life cycle. The bacteria secrete enzymes that favor the oxidation of iron. Thus, at local anodes where ferrous hydroxide is formed, this quickly turns into ferric and carbonated hydroxide by dissolved oxygen and carbon dioxide. Generally, the microbial process ends there; however, the rapid transformation of the ferrous ions into ferric salts, results in the formation of a voluminous clump of 'rust' containing the bacterial bodies, sometimes known as a tubercule, followed by a continuing attack of the metal.<sup>98</sup> The local environment under the rust is likely to be depleted in oxygen and this can provide a microclimate for the proliferation of anaerobic microbial species.

### 3.02.5.13.2 Sulfate-metabolizing bacteria

Sulfate-reducing bacteria, being anaerobic in nature, are found under the layers of rust, in contact with the metal, where oxygen does not reach them. They generally transform sulfate into reduced sulfur species ending in hydrogen sulfide, which combines with the ferrous salts to produce a black sulfide for example:

With the overall reaction:

Sulfur oxidizing bacteria, for their part, metabolize sulfur from sulfur or sulfide compounds, resulting in the production of sulfite or sulfate species and acidification of the medium, causing severe corrosive attack. For example:

Historically, microbial oxidation of ferrous sulfide (e.g., in tin, lead, and coal mines) resulting in the formation of strongly acidic mine waters, provided the first industrial examples of this type of corrosion.

However, it is also found in many industrial water circuits (water sprinkler system, for example). In favorable circumstances, colonies of sulfate reducing and sulfate oxidizing bacteria may coexist giving rise to serious corrosion problem in water transport and in particular, the sewerage systems. The following conditions are generally favorable to biological corrosion by sulfur bacteria: an anaerobic medium, a pH of 5.5–8.5, the presence of sulfates, the presence of a food (carbon) source, the presence of essential nutrients such as phosphate, and an optimal development temperature (e.g.,  $30$ – $40^{\circ}\text{C}$ ).

### 3.02.5.13.3 Mechanisms of action

Together, microbiological knowledge of bacterial metabolisms and knowledge of corrosion on the chemistry of water in the presence of acid gases  $\text{CO}_2$  and  $\text{H}_2\text{S}$ , lead to the conclusion that sulfate-reducing bacteria can regulate the pH of their environment to favor their growth. Secondary reactions with traces of oxygen or of ferrous iron can modify this pH value.<sup>99</sup>

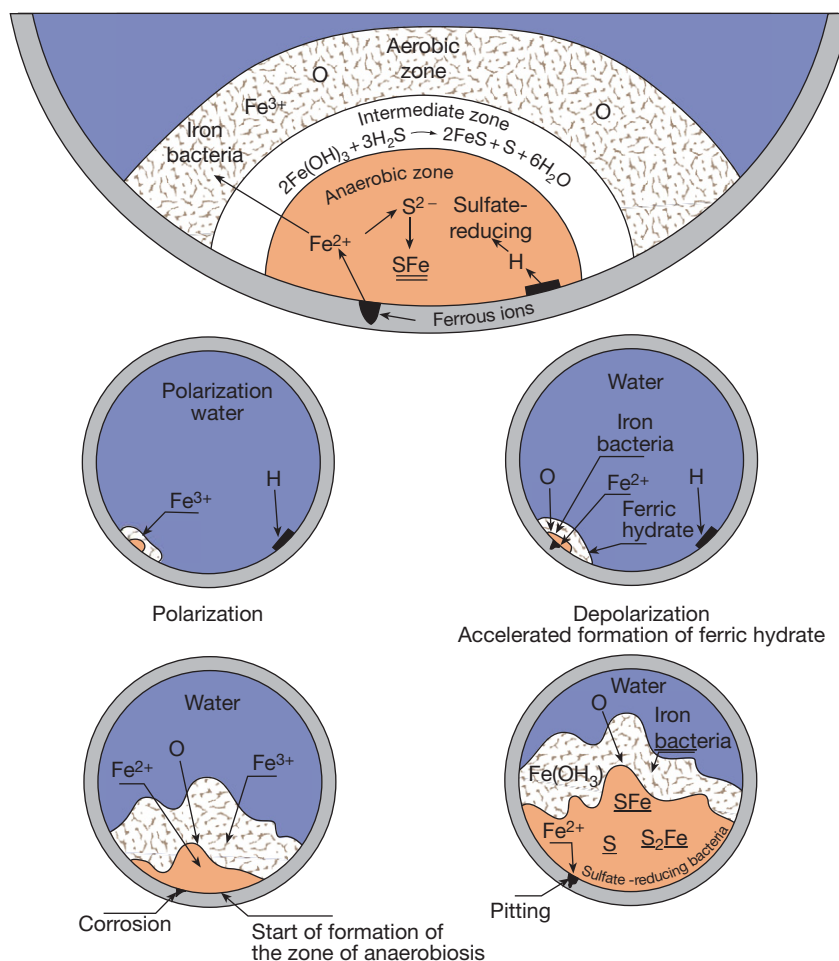

It is important as well to remember that corrosion that occurs in an anaerobic medium is not necessarily bacterial; it may well be just a sign of the activity of a macrocell of the differential aeration type at its anodic zones, located precisely in the anaerobic zone. In the case of extended structures, these two types of activity are often found superimposed. Also, bacterial corrosion may be observed in soils that are not strictly anaerobic, but in which, as a result of corrosion previously initiated by classical processes, conditions favorable to the spread of bacterial activity have been established, for example under the corrosion product layers.

### 3.02.5.13.4 Microbial corrosion of cast iron

Often, the formation of a gelatinous vesicle is an initial visible sign of bacterial attack. This vesicle takes the form of a brown mass with smooth contours containing a blackish liquid with a strong hydrogen sulfide odor. At this stage sulfur compounds such as S, FeS, and  $\text{FeS}_2$  are present in the gelatinous mass, which conceals corrosion, usually in the form of a crater that may perforate the metal. The craters contain pockets of bacteria, commonly with iron bacteria near the surface and sulfate-reducing bacteria in the interior, which is anaerobic. Generally, biological corrosion almost always follows as a result of electrochemical corrosion but can increase it substantially.

The process of development of corrosion vesicles on cast iron is shown schematically in **Figure 37**. From the outset, the ferrous ions that form at the

**Figure 37** Formation of a gelatinous vesicle during microbial corrosion. Based on a figure in Badan, B.; Magrini, M.; Ramous, E. *J. Mater. Sci.* **1991**, 26, 1951–1954, and reproduced with permission from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

anode are transformed by oxidation into ferric hydroxide and hence, form a layer of rust, which gradually impregnates with ferrous salts that diffuse on the surface. These ferrous salts taken up by iron bacteria are quickly transformed into ferric hydroxide under aerobic conditions, and because of this the volume of the mass increases. It becomes more and more difficult for oxygen to diffuse to the interior. Aerobic development bacteria, therefore, can only thrive in the peripheral layers. This process creates, in the underlying layer, anaerobic conditions favorable to the development of sulfate-reducing bacteria, which reduce sulfates into hydrogen sulfide and iron sulfide. An Italian study<sup>100</sup> has confirmed the mechanisms stated above for microbial corrosion, in particular the formation of corrosion tubercles on the inside surface of cast iron pipes. In practice, in the

case of water delivery pipes, cement mortar linings have been used for nearly 50 years as a mechanism for controlling corrosion in new pipes and for renovation of old pipes.

### 3.02.5.13.5 Combating microbial corrosion

Many chemicals (biocides) can, in principle, be used to combat bacterially influenced corrosion. Among these include oxidizing agents (e.g., chlorine, bromine, potassium permanganate, etc.), toxic heavy metals (e.g., Ag, Cu, Zn, Hg), and their salts, detergents and amine derivatives, and aromatic alcohols (e.g., phenol and derivatives). These compounds are extremely varied, but often have high toxicity not only to the microbial species, but also to other lives. The use of many of these is controlled by legislation over the discharge of materials is the

environment. Chantereau's book<sup>98</sup> contains a list of the main products used in the fight against bacteria, with all their characteristics and domains of use. Note that chlorine, even though it is normally a corrosive substance, is beneficial in this context; its bactericidal action generally reduces corrosion by two thirds.

### 3.02.5.14 Flow-Induced Corrosion

#### 3.02.5.14.1 Cavitation corrosion of cast iron

When a liquid is subjected to a sudden fall of pressure, bubbles of vapor having a life of the order of a millisecond may form. This extremely brief existence ends when the local pressure increases in an implosion that, repeated thousands of times, can cause significant damage to some equipment. This is the phenomenon of cavitation. Some authors<sup>101</sup> have shown the impact of cavitation on corrosion damage: a ratio of 1–75 000 between 'simple' corrosion rates and cavitation corrosion rates. The interested reader may refer to Heuze<sup>102</sup> and for a theoretical examination of the phenomenon. In practice, two main types of cavitations are distinguished: 'flow' cavitation, which affects for example the vanes of turbines, and cavitation by vibrations. In cavitation by vibrations, the formation and implosion of bubbles result from the shock waves that a vibrating surface produces.

The apparently complex influence of temperature on the cavitation corrosion of cast irons has been the object of several studies.<sup>103–105</sup> It has, for example, been shown that the maximum attack occurs at a temperature approximately mid-way between the boiling and melting points of the corrosive medium (60 °C, in the case of water).<sup>104</sup> This critical temperature is assumed to be located differently according to the nature of the liquid and the ambient pressure.<sup>106</sup> It is found, in the case of water, that the deterioration of the material increases as the temperature rises from 0 to 50 °C. This seems to be explained by the concomitant lowering of the dissolved air content. Above 50 °C, the intensity of the cavitation decreases as the temperature increases; the lower air content of water is then offset by the higher vapor pressure. The nature of the fluid is also of some importance. Non-ionic liquids, such as toluene, are much less aggressive than water in the context of cavitation. The high vapor pressure of these liquids is invoked to explain this point. Otherwise, concerning the inhibition of this type of corrosion, in closed systems (cooling circuits), sodium nitrite or chromate and a few amines (triethanolamines, for example) have been proposed. The effectiveness of this protection by

inhibitors proves the importance of the electrochemical factor in cavitation corrosion.

Cast irons as a whole are said to be more sensitive to cavitation than steels. Certain authors<sup>107–110</sup> have shown that pearlitic cast irons are less vulnerable to cavitation than ferritic grades, and that the shape and size of the graphite inclusions also play a role on the spheroidal graphite cast irons being more resistant. Often surface hardening can improve the resistance to cavitation corrosion and studies have shown the utility of a superficial nitriding treatment.<sup>110,111</sup> Otherwise, austenitic spheroidal graphite cast irons from 20% Ni, 2% Cr to 30% Ni, 5% Cr display excellent resistance to cavitation corrosion under the most severe conditions. Thus, fishing-boat propellers and pump rotors made of these materials provide better service than a bronze or a stainless steel containing 18% chromium, **Table 31**.<sup>84</sup>

Some laboratory studies have simulated cavitation phenomena using sonic or ultrasonic vibrations.<sup>112</sup> In one of these studies, the vibrations were of 40 µm in amplitude at 15 kHz. In such operating conditions, the losses of mass of the four types of cast iron were as follows: ferritic lamellar graphite cast iron: 298 mg h<sup>-1</sup>; pearlitic lamellar graphite cast iron: 155 mg h<sup>-1</sup>; ferritic spheroidal graphite cast iron: 124 mg h<sup>-1</sup>; pearlitic spheroidal graphite cast iron: 67 mg h<sup>-1</sup>. It was found that the intensity of the corrosion cavitation was proportional to the square of the amplitude of the vibrations. However, the general rates of cavitation corrosion in this type of laboratory test are much larger than those in the field.

Cavitation is not an uncommon problem in internal combustion engines using cast iron cylinder liners. It has been shown<sup>113</sup> that the radial vibrations of the walls of the lining due to the running of an engine can lead to severe cavitation damage of the cast iron. Other work has shown that the superimposition of an external mechanical effect (tension or compression) does not appear to affect the intensity

**Table 31** Cavitation corrosion of various cast irons in seawater

of the cavitation phenomenon (provided that it does not give rise to a significant stress phenomenon).

Some authors<sup>114</sup> have shown that the cavitation corrosion resistance of a lamellar graphite cast iron that has undergone superficial laser surface alloying by chromium (22%) in water (with or without 3% NaCl) at 50 °C is greatly increased. Similarly, other authors<sup>109</sup> have also shown the value of a surface hardening treatment. They found that a nitrided layer having the right hardness, thickness, and homogeneity is a good means of defence against cavitation corrosion.

An outline review of the literature on resistance of cast irons to cavitation<sup>109</sup> identified, or served to recall, a certain number of preliminary ideas. For example, it is known that the weakening effect of the graphite lamellae depends on their size, shape, and distribution in a given matrix. The spheroidal shape is optimal in this respect. Similarly, hard matrices (martensitic, bainitic, etc.) are preferable (the martensite must be tempered). Otherwise, note that saline solutions (3% NaCl) are much more aggressive than distilled water (up to seven times as corrosive). The use of inhibitors or of cathodic protection can be very effective. The presence of phosphorus (of phosphorus eutectic) has little effect other than a possible reduction of the incubation time of the phenomenon. Silicon, unlike chromium and molybdenum, increases cavitation resistance.

Kuwaiti researchers in 2001 studied the mechanisms of degradation of spheroidal graphite cast irons subjected to cavitation effects in seawater. They showed that the surfaces of iron castings, hollowed as wide craters, are prolonged in the cast iron by microcracks. The mechanism of initiation of the degradation seems to be related to the activity of a galvanic microcouple at the graphite–ferrite interface; the process is then prolonged by brittle fracture and ductile tearing of the material.<sup>97</sup>

### 3.02.5.14.2 Corrosion–erosion of cast iron

When the corrosive liquid also contains abrasive particles, there appears a phenomenon of erosion that strips away the corrosion products as they form, keeping the metal bare and therefore active. This mode of attack is commonly called ‘corrosion–erosion’ or ‘erosion–corrosion’ (the terms are often used interchangeably, but see below) or possibly ‘cavitation–erosion’ when the flow becomes highly turbulent.<sup>115,116</sup> The phenomenon of abrasion–corrosion (more correctly erosion–corrosion) is the result of mechanical damage by the action of solid

particles and electrochemical damage due to the presence of a corrosive medium. This type of situation is often found in industry, for example in treatment and transport of fluids in the oil and mining industries. Many parameters are influential on the damage: for example, the shape, hardness, size, and velocity of the particles, angles of incidence, characteristics of the medium, etc. Gray cast irons can be used, given their low cost price, if the erosion conditions are not too severe. However, significant performance benefits accrue using more resistance materials such as a ‘Ni-Hard’ grade. Lower alloyed materials have carbides predominantly as  $M_3C$  type and, in order to obtain increased resistance to erosion effects, the chromium and nickel contents must be increased to irons largely free of pearlite and containing harder carbides of the  $M_7C_3$  type.

Examination of the corrosion morphology of cast iron under erosion–corrosion conditions reveals that the erosion process generally begins with attack of the softer graphitic phase creating, in LG irons particularly, a network of voids that facilitates the penetration of the aggressive liquid. It follows that fine lamellar graphite is preferable to coarse lamellar graphite. After the preliminary stage, cracks form, essentially at the pearlite–phosphorus eutectic interfaces and at the boundaries between the various colonies of pearlite, leading to a gradual loss of cohesion of the cast iron. Ferrite seems to stand up better to this erosion process.

An ever-growing quantity of cast iron having high chromium and molybdenum contents is being used for the production of pumps that are harder and more resistant to abrasion. The results of tests on cast irons containing 15% Cr + 2% Mo or 25–27% Cr have, moreover, been published.<sup>117</sup> In this case, the advantages with respect to low-alloy white cast irons lie not only in their greater abrasion resistance and better fracture toughness, but also in their improved machinability. The housing and rotors of pumps transporting abrasive muds and of dredging pumps are manufactured by techniques that include annealing, machining, and quenching.<sup>118</sup> Elastic coatings to absorb impacts can also be considered.

High-chromium alloys with carbon contents in the range 0.5–2.0% afford a useful compromise between resistance to corrosion and resistance to abrasion. As the carbon content is increased, the resistance to abrasion improves, but corrosion resistance is reduced. The matrix structure of this range of high-chromium alloy irons can be largely austenitic or can be transformed to martensite by heat

treatment. There has been an increased interest in this series of alloy irons in recent years because they would seem to offer a cost-effective solution to problems encountered in handling abrasive slurries arising from gas scrubber installations in coal-fired power stations, **Figure 38**. They are also seen as candidate materials for the high-speed high-pressure pumps necessary in coal liquefaction projects, since they are able to resist abrasion at temperatures at which many abrasion-resistant steels would soften.

It is to be remembered that the hardness of the metal is not the only parameter to be considered in predicting resistance to corrosion-erosion. Allowance must also be made for factors related to the microstructure of the alloy, for example the size of the particles transported by the fluid relative to the size of the 'matrix' constituent. If the particle sizes are larger than the mean size of an 'island' of matrix in the microstructure, there will be less wear. There is a longstanding tendency to believe that, in these corrosion-erosion phenomena, the share of erosion prevails over the share of corrosion. In the light of certain tests, there seems to be less and less reason to believe this. Japanese authors<sup>119</sup> have shown that the erosion-corrosion of chromium cast irons is initiated at the matrix-carbide interface, and subsequently continues as corrosive and abrasive wear of the matrix

that can be reduced by increasing the chromium content. In general, additions of vanadium (5–8%), molybdenum (1–2%), and titanium (0.2%) seem to be effective ways to increase the resistance of grades containing 12–13% chromium.

Another Japanese study<sup>120</sup> has shown that the corrosion-erosion resistance of cast irons is often less than that of steels, because the preferential stripping of the graphite leads to the formation of craters, in which localized forms of corrosion are then initiated. These same authors have also shown that the deterioration of the material is inversely proportional to its hardness and that it can be prevented by cathodic protection. An electrochemical study of the corrosion-erosion resistance of white chromium cast irons has shown that the anodic corrosion current increases as the velocity of the abrasive substance increases and as the chromium content of the cast iron decreases.<sup>121</sup> Other work<sup>122</sup> has shown the value of austenitic-martensitic cast iron containing 5% manganese and 3% copper against corrosion-erosion, which would seem to have the same characteristics as a high-nickel alloyed grade. Finally, according to the same authors, a complementary addition of copper to chromium cast irons (5–6%) would seem to increase their resistance to this type of corrosion.

Many publications<sup>123,124</sup> report that laser surface hardening considerably increases erosion-corrosion resistance. Tests mentioned by American authors<sup>125</sup> have shown that, with gray cast irons (LG and SG), high power densities and long laser-cast iron interaction times result in very high hardness values (1200–1300 HV). The microstructures then observed correspond to fine carbide-ferrite aggregates. If the power density and interaction time are reduced, the hardness values are lower (600–800 HV) and the microstructure is found to be made up of dendrites of metastable austenite and films of interdendritic cementite. Depending on the values given to the various parameters of the laser treatment, the corrosion-erosion resistance can be improved by a factor of 2–5.

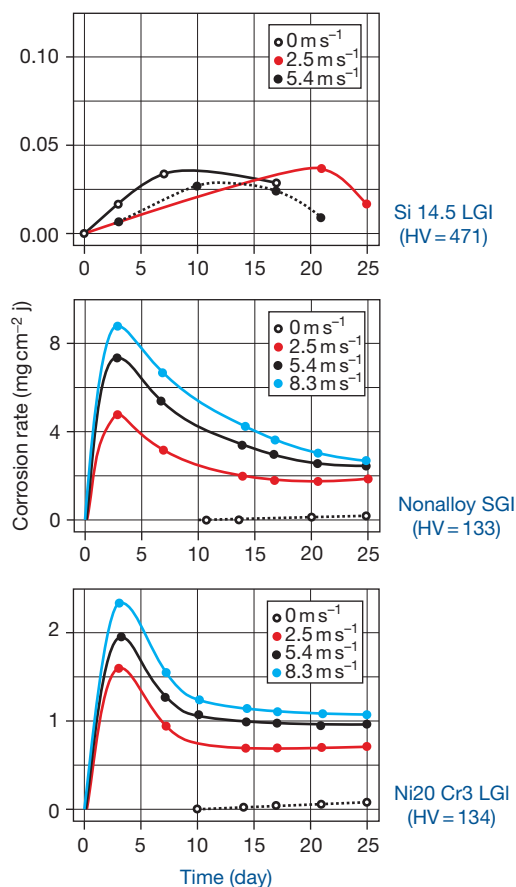

In the salt-rich and very polluted waters of the Persian Gulf, a comparative study of the corrosion-erosion resistance of a ferritic unalloyed SG cast iron, a silicon cast iron (14.5% Si), an austenitic lamellar graphite cast iron containing 20% Ni and 3% Si, and a duplex cast steel similar to a G-X 3 CrNiMo 26 6 3 cast steel with a reduced manganese content was carried out.<sup>126</sup> The objective was to test materials for ball valves. During these tests, the mechanism of corrosion and the formation of protective layers were also studied. The duplex cast steel suffered no measurable attack in the course of

**Figure 38** Influence of pH value on weight loss in the slurry abrasion test.

25 days of tests. The corrosion losses of the three grades of cast iron are shown in **Figure 39**.

In stagnant water, only a small loss occurs, while in turbulent water the erosion increases significantly at first, except in the case of silicon cast iron where a coating made up of corrosion products forms.

**Figure 39** Corrosion rates of three grades of cast iron in turbulent Persian Gulf seawater at 28 °C.

Gradually, the corrosion slows and the influence of the current velocity becomes weaker and weaker and forms, on the surface of the specimens, a thicker and thicker coating of corrosion products that slows the attack.

**Table 32** indicates the masses of the coating of corrosion products measured on the three grades of cast iron. On the silicon cast iron, the layer is very thin. At low current velocities and in still water, a phenomena similar to pitting or intergranular corrosion appeared on the cast irons; on the graphite lamellae and in the zones of segregation between the dendrites in particular. At higher current velocities, these phenomena disappear and the level of corrosion regresses to values too small to measure. The silicon cast iron suffered the least attack at all current velocities, thanks to its hardness, 470 HV, and to the thick coating of SiO<sub>2</sub>.

Some authors<sup>127</sup> have proposed two grades of white cast iron containing manganese (4–5%) and chromium (5–6%), with and without copper (0 and 2–3%), that seem to have the same corrosion–erosion resistance as an austenitic–martensitic white nickel–chromium cast iron of the ‘Ni-Hard’ type; the addition of copper seems to increase the corrosion resistance. Ageing these grades for 6 h at 800 °C is recommended, in order to precipitate very fine carbides in the austenitic matrix to increase the erosion resistance.

### 3.02.6 Corrosion by Gases

#### 3.02.6.1 High Temperature Oxidation and Corrosion

At temperatures above ~500 °C, unalloyed cast iron in an oxidizing atmosphere becomes covered with a

**Table 32** Mass of corrosion product on cast iron after exposure to seawater at different flow velocities

scale made up of several layers of oxides plus a layer consisting of ferrous oxide and oxides of the alloy element X:  $\text{FeO} + \text{Fe}_y\text{X}_z\text{O}$ . Thus, its behavior is very similar to steel under the same conditions. The effect of chromium, aluminum and silicon additions to cast iron alloys on oxidation at high temperature has long been known. Thus, alloyed irons preferentially form more protective oxide scales consisting of, respectively,  $\text{Cr}_2\text{O}_3$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{SiO}_2$ . Reaction with  $\text{FeO}$  at the oxide-metal interface may additionally result in the formation of a spinel:  $\text{FeCr}_2\text{O}_4$  or  $\text{FeAl}_2\text{O}_4$ , or a silicate such as  $\text{Fe}_2\text{SiO}_4$ . At greater distances from the basic metal, the oxygen pressure increases and, at a certain level,  $\text{FeO}$  is transformed into  $\text{Fe}_3\text{O}_4$ , then  $\text{Fe}_2\text{O}_3$ . The diffusion velocity of the iron ions in the lower layer of compound oxides, highly adherent and more compact than the superficial layers of pure iron oxides, is very low and hence, protects alloys containing chromium, aluminum, and silicon. The presence of molybdenum also favors this oxidation resistance.

In this particular case of lamellar graphite cast irons,<sup>128</sup> oxidation at high temperature is not limited to the superficial layer, but progresses along the graphite-matrix interfaces in the interior of the casting. The oxygen first combines with carbon, which at the temperatures in question gives carbon dioxide,

**Figure 40** Superficial oxidation of a unalloyed cast iron held in air at a temperature of 900 °C (the initial specimen was 10 mm in diameter and 30 mm long). Reproduced with permission from Sawamoto, A.; Usami, T.; Ogi, K.; Matsuda, K. *Imono* **1984**, 10, 597–601.

$\text{CO}_2$ , which in turn oxidizes the metal as it turns into  $\text{CO}$ . This gas tends to crack the protective oxide film, thereby facilitating the entry of oxygen. The formation of the oxidized compounds combines with the graphitization to cause a swelling of the cast iron. The progression of the oxidation, therefore, follows the path traced by the graphite; the layers of oxides are interposed between the matrix and the graphite lamellae.

Figure 40 below gives an idea of the intensity of the superficial oxidation that occurs when gray cast iron is held at 900 °C in air. Generally, the relative importance of the layer of oxides formed is measured using the change of mass of the sample. The absorption of oxygen is reflected by an increase of the mass due to the formation of the layer of oxides, while the removal of this layer causes a reduction of this mass. For specific graphite contents, the lamellar shape is therefore the most unfavorable; resistance to the penetration of the oxidation increases as the shape becomes more compact, with the spheroidal shape being the most favorable. Figure 41, which compares the swelling of five lamellar graphite cast irons having different silicon contents with the swelling of five spheroidal graphite cast irons having the same composition, shows the superiority of the latter very clearly.

A Japanese study of the effect of chromium, aluminum, nickel, and silicon on the oxidation rate of SG cast irons between 700 and 850 °C was

**Figure 41** Samples 10 cm long were subjected to cycles of heating (30 min at the temperature indicated) and cooling in air. Reproduced with permission from Bechet, S. *Hommes Fonderie* **1981**, 112, 15–28.

**Figure 42** Oxidation behavior at high temperature of various SG cast irons held for 100 h at 700 and 850 °C.

investigated<sup>129</sup> with the elements classified in order of decreasing effectiveness, as follows: Si–Cr–Al–Ni. Information on the influence of moderate additions of chromium, aluminum, nickel, and/or silicon on oxidation resistance at high temperature is shown in **Figure 42**.<sup>130</sup>

The beneficial effect of chromium on the oxidation resistance of cast irons is shown in **Figure 43**. This effect is very substantial from the first additions of chromium; this is a significant advantage, given that the chromium content of gray cast irons is always limited because of its strong tendency to produce carbides, which can for example result in machining difficulties.

In general, the types of cast iron used as a function of temperature are as follows:

- cast iron at 1–2% chromium for combustion gas with temperatures of not more than 850 °C or for preheating, up to a maximum of 350 °C, of gas having a high carbon monoxide content;
- cast iron at 30% chromium in the case of combustion gas of which the temperature is less than or equal to 1050 °C, or for the preheating of air to 650 °C.

The resistance of 30% chromium cast iron to destruction by gases having high carbon monoxide content is excellent in the temperature range from 400 to 600 °C.

The influence of the silicon content in conjunction with the carbon content shows that the oxidation resistance of hypoeutectic cast irons is better than that of hypereutectic cast irons. The harmful effect of carbon is also recognized. The influence of silicon content (between 2.4% and 6.4%) on the oxidation of five SG cast irons as a function of temperature is evident in **Figure 44**. This figure clearly shows that

**Figure 43** Influence of chromium on the oxidation of cast irons at 800 °C. Reproduced with permission from Murakami, N.; Kobayashi, T. Owadano *Imono* **1986**, 58(7), 275–280.

the higher the temperature, the more important the role of silicon.

Certain American tests measured oxidation depths of 0.18 mm in a eutectic cast iron containing 4.7% silicon and 0.025 mm in a eutectic cast iron containing 5.9% Si, after exposure in air at 870 °C for 1000 h. It follows that increasing the silicon content very quickly reduces oxidation at high temperature.

Oxidation resistance is also greatly improved by the addition of aluminum. **Figure 45** illustrates the oxidation resistance of a cast iron containing 3% C and 0.8% Si as a function of its aluminum content (2.4, 4.3, and 6%), after 200 h exposure to temperatures up to 980 °C. **Figure 46** shows the influence of

**Figure 44** Influence of silicon content on the oxidation resistance of SG cast irons as a function of temperature. Reproduced with permission from Murakami, N.; Kobayashi, T. Owadano *Imono* **1986**, 58(7), 275–280.

**Figure 45** Influence of aluminum content on oxidation resistance of cast irons containing 3% C, exposed for 200 h at the temperature indicated. Reproduced with permission from Murakami, N.; Kobayashi, T. Owadano *Imono* **1986**, 58(7), 275–280.

aluminum content on the oxidation resistance of gray cast irons as a function of temperature. Otherwise, with aluminum contents of the order of 20–25%, there is practically no oxidation:  $\sim 20 \text{ mg m}^{-2} \text{ day}^{-1}$  at  $1050^\circ\text{C}$ .

Combining silicon with aluminum provides significant improvement in oxidation resistance. The best resistance to oxidation at  $950^\circ\text{C}$  compatible with acceptable mechanical properties seems to be

obtained with fine graphite cast irons containing 6.5–7% Al and 5–6% Si; better performance occurs with a carbon content close to the eutectic, that is, close to 1.8% C. The addition of aluminum also increases the resistance of cast iron in a sulfurous atmosphere. There is literature evidence<sup>128</sup> that the lowest oxidation rate occurs in alloys having compositions close to 5% Al, 2% Mo, and 2–3% Si: the penetration of oxidation in a cast iron of this type, after 1000 h at  $925^\circ\text{C}$ , is  $8 \mu\text{m}$ . The resistance of some spheroidal graphite high-nickel high-alloy cast irons (e.g., 30% Ni, 5% Cr, 5% Si) to heat and to corrosion by hot gases, chlorine, and chlorides is excellent.<sup>131,132</sup> Their drawback is that they are very expensive. Otherwise, the resistance of ‘Ni-Resist’ cast irons to oxidation at high temperature is generally high. They are often used for certain applications, such as exhaust manifolds for extreme conditions and some turbocharger parts.<sup>133</sup>

### 3.02.6.2 Corrosion by other Gas Atmospheres

A precise, exhaustive treatment of this subject would greatly exceed the scope of this article. Thus, a few general remarks for a few of the most commonly encountered corrosive gases will be made.

Cast irons stand up rather well to hydrogen sulfide gas from  $-60$  to  $+20^\circ\text{C}$  provided it is dry; otherwise, there is risk of a form of hydrogen cracking.<sup>134</sup> The losses of thickness, in the case of a mixture of 98%  $\text{H}_2\text{S}$  and 2% air at  $32^\circ\text{C}$ , are  $0.075 \text{ mm year}^{-1}$  ( $1.75 \text{ mm year}^{-1}$  for damp  $\text{H}_2\text{S}$ ) for unalloyed cast irons and  $0.050 \text{ mm year}^{-1}$  for austenitic cast irons. At higher temperatures, cast irons perform satisfactorily (especially unalloyed cast irons); the losses of thickness are shown in Table 33. Silicon cast irons are also relatively resistant to hydrogen sulfide up to  $100^\circ\text{C}$ . The presence of chromium, even at moderate contents (2%), improves resistance to this gas; such cast irons in fact have acceptable performance up to  $300^\circ\text{C}$ .

In hot sulfur dioxide, the gas temperature significantly affects the corrodibility of cast iron. Thus, in roasting furnaces (8%  $\text{SO}_2$ ), an SG cast iron containing 0.5% Cr is acceptable provided the temperature remains below  $300^\circ\text{C}$ . At  $550^\circ\text{C}$ , it is still possible to use an ordinary cast iron provided that it is metallized by spraying with aluminum; at higher temperatures, at  $1000^\circ\text{C}$ , it becomes necessary to use a cast iron containing 30% chromium or 16% silicon and 3% molybdenum.

**Figure 46** Influence of aluminum content on the oxidation resistance of gray cast irons containing 6% Si and 2% C. Reproduced with permission from Murakami, N.; Kobayashi, T. Owoodano *Imono* **1986**, 58(7), 275–280.

**Table 33** Corrosion of cast iron in hydrogen sulphide

Medium	Loss of thickness (mm year <sup>-1</sup> )	
	Unalloyed cast irons	Austenitic cast irons
H <sub>2</sub> S at 80–85°C	0.64	0.21
H <sub>2</sub> S at 92°C	1.75	0.25

At ordinary temperatures (and at low temperatures), dry gaseous (or liquid) chlorine does not attack cast irons. Also, provided that the temperature is sufficient to avoid water condensation, chlorine containing some water vapor is not significantly aggressive. However, at higher temperatures, above ~350°C, chlorine reacts with water vapor to form hydrochloric acid and hypochlorite, which is highly aggressive and requires the use of high-alloy cast irons (e.g., containing 15% silicon and 3% molybdenum or Ni14Cu6Cr3 ‘Ni-Resist’ LGI cast irons or again cast irons containing 30% chromium). **Table 34** indicates the corrosion rates of a unalloyed cast iron and of carbon steel in chlorine as a function of temperature.<sup>135</sup>

Specific studies of corrosion risk are often performed for recuperators and heat exchangers for the cooling or heating of air that may contain chlorine traces. This is because, among the many causes of corrosion of heating installations, there is one that is especially insidious, namely corrosion by the action of halogens in air.<sup>136</sup> Note that any halogen present in

**Table 34** Corrosion of cast iron in chlorine gas as a function of temperature

Alloy	Temperature (°C)	Corrosion rate (mm year <sup>-1</sup> )
Unalloyed LGI	93	0.76
	120	1.52
	177	3.05
	232	30.00
	280	0.76
18–8	315	1.52
	400	15.20

a combustion atmosphere potentially react to produce aggressive products such as HCl. Halogen sources include chlorinated substances that have household, industrial, and recreational uses and, hence, incineration of wastes can produce a highly aggressive atmosphere.

Given the very large number of gases and mixtures of gases, an exhaustive study is impossible, so **Tables 35** and **36** indicate the cast irons recommended for given gas conditions.

### 3.02.6.3 Corrosion in Gas Transport and Distribution Pipes

The gas flowing in these pipes may, in the course of its travel, either remain at all times at a temperature above its dew point or occasionally cool to a temperature below this dew point. In the former case,

**Table 35** Recommended cast irons for use in the specified gas atmosphere

<i>Gaseous mixture</i>	<i>Recommended cast iron</i>
<b>Mixture</b>	
<i>Gas mixture with CO<sub>2</sub> or CO<sub>2</sub> + CO</i>	
+ CO <sub>2</sub> (95 %) + H <sub>2</sub> O (2,5 %) + NH <sub>3</sub> (1,5 %)	'Ni-Resist' cast iron
+ CO <sub>2</sub> (87 %) + H <sub>2</sub> O (2 %) + inert gases (11 %) NH <sub>3</sub> (traces)	'Ni-Resist' cast iron
+ CO <sub>2</sub> (70 %) + air (16 %) + H <sub>2</sub> O (10 %) + NH <sub>3</sub> (4 %)	'Ni-Resist' cast iron
+ CO <sub>2</sub> (17 %) + CO (25 %) + H <sub>2</sub> O (2 %) + H <sub>2</sub> (50 %) + N <sub>2</sub> (4 %) + CH <sub>4</sub> (52 %)	'Ni-Resist' cast iron or 15% Si cast iron
+ CO <sub>2</sub> (13 %) + CO (11 %) + H <sub>2</sub> (7 %) + O <sub>2</sub> (2 %)	15% Si cast iron or ferritic white Cr+Mo cast iron
+ CO <sub>2</sub> (11.6 %) + N <sub>2</sub> (77 %) + H <sub>2</sub> O (8 %)	'Ni-Resist' cast iron or 15% Si cast iron
+ CO <sub>2</sub> (5 %) + N <sub>2</sub> (74 %) + H (20 %) + O <sub>2</sub> + CH <sub>4</sub> + CO (1 %)	Unalloyed cast iron
+ CO <sub>2</sub> (4 %) + CO (70 %) + N <sub>2</sub> (18 %) + H <sub>2</sub> (6 %) + water and hydrocarbon vapours	1.5% Ni Pearlitic LGI
+ CO <sub>2</sub> (0.5 %) + H <sub>2</sub> O (6.6 %) + air (93 %)	Unalloyed cast iron
<i>Gas mixture with CO<sub>2</sub> and SO<sub>2</sub></i>	
+ CO <sub>2</sub> (10 %) + SO <sub>2</sub> (17 %) + O <sub>2</sub> (10 %) + N <sub>2</sub> (63 %)	Unalloyed cast iron
+ CO <sub>2</sub> (12 %) + SO <sub>2</sub> (0.1 %) + O <sub>2</sub> (3.4 %) + N <sub>2</sub> (74.5 %) + water vapour (10 %)	'Ni-Resist' cast iron
+ CO <sub>2</sub> + SO <sub>2</sub> (0.3 %) saturated with moisture	'Ni-Resist' cast iron
<i>Gas mixture with SO<sub>2</sub>, SO<sub>3</sub>, SO<sub>2</sub> + SO<sub>3</sub>, or SO<sub>2</sub> + NO<sub>2</sub></i>	
+ SO <sub>2</sub> (18 %) + N <sub>2</sub> (79 %) + O <sub>2</sub> (3 %)	Unalloyed cast iron
+ SO <sub>2</sub> (8 %) + N <sub>2</sub> (79 %) + O <sub>2</sub> (13 %) nearly dry (50 mg/m <sup>3</sup> H <sub>2</sub> O)	300 LGI, 1.8% Ni and 0.6% Cr
+ SO <sub>3</sub> (9 %) + N <sub>2</sub> (85 %) + O <sub>2</sub> (6 %) dry	Unalloyed cast iron
+ SO <sub>2</sub> + SO <sub>3</sub> (traces) dry (30°C)	2% Ni SGI
+ SO <sub>2</sub> (9.5 %) + NO <sub>2</sub> (84.7 %) + air (5.8 %) dry	Unalloyed cast iron
<i>Other gas mixtures</i>	
+ H <sub>2</sub> saturated with water + O <sub>2</sub> (3 %) + Cl <sub>2</sub> (2 ppm) (35°C)	'Ni-Resist' cast iron, Ni15 Cu5 Cr2 LGI
+ HCl (50 %) + N <sub>2</sub> (50 %) (dry)	Unalloyed cast iron
+ HCl (50 %) + N <sub>2</sub> (50 %) (dry) (damp)	15% Si cast iron
+ Vinyl chloride saturated with water vapour (36–100°C)	Unalloyed cast iron
+ O <sub>2</sub> Damp + CO <sub>2</sub>	'Ni-Resist' cast iron
+ Perchloric vapours	15% Si cast iron
+ CH <sub>4</sub> (62.5 %) + CO (12 %) + H <sub>2</sub> (5 %) + N <sub>2</sub> (10.4 %) + CNH <sub>2</sub> N (8.7 %) + O <sub>2</sub> (1.5 %)	Unalloyed cast iron
+ Dimethylether (38 %)/Methanol (27 %) + N <sub>2</sub> (28 %) + O <sub>2</sub> (3 %) + H <sub>2</sub> O (3 %) + CO <sub>2</sub> (1 %) + CO	Unalloyed cast iron
+ H <sub>2</sub> S (60–68 %) + CO <sub>2</sub> (22–28 %) + HCN (6–8 %) + water vapour (4 %)	None
+ H <sub>2</sub> S (13.4 %) + CO <sub>2</sub> (34 %) + HCN (1.5 %) + H <sub>2</sub> (24 %) + CO (22 %) + sodium aluminate (4.5 %) dry	Unalloyed cast iron
+ Air + heavy water (vapour)	'Ni-Resist' cast iron
+ Monochlorobenzene vapour saturated with water	15% Si cast iron

Data taken from Reynaud, A. *Corrosion and Cast Iron*, ETIF, France, 2008.

there is no condensation, while in the latter water is deposited. Such condensates are likely to form a thin film of moisture, continuous or not, which can lead to corrosion generally at the base of the pipes. For this reason, gas networks have traps, to be able to eliminate condensates. When this is done, centrifugal cast iron pipes only rarely suffer this type of internal corrosion due to the gas transported, even

if it contains water vapor. Industrial experience has in fact shown that the cast iron tubes used for natural gas distribution can survive for many decades without undergoing significant internal corrosion. In the case of oxygen-free natural gas, the principal aggressive constituents are sulfides. However, distributors will purify and condition gases so as to avoid these phenomena.

**Table 36** Recommended cast iron for use in specified gas atmosphere

Gaseous mixture	Recommended cast iron
Pure gases	
H <sub>2</sub> 100 % – 49°C	'N-Resist' cast iron (Ni23 Mn4 SGI)
HCl 100 %	32–34% Chromium cast iron
NH <sub>3</sub> 100 %	Unalloyed cast iron
Freon 113 – 50°C	Unalloyed cast iron
CCl <sub>4</sub> , dry, 40°C	Unalloyed cast iron
CCl <sub>4</sub> , damp, 40°C	'Ni-Resist' cast iron
Phenols (vapours)	Unalloyed cast iron
Acetone	Unalloyed cast iron
Toluene	Unalloyed cast iron
Ethanol	Unalloyed cast iron
Haptane	Unalloyed cast iron
NO, dry	Unalloyed cast iron
NO <sub>2</sub> dry	Unalloyed cast iron
Propane	Unalloyed cast iron
Bulane	Unalloyed cast iron
Ethane	Unalloyed cast iron
Mathane	Unalloyed cast iron
Ethylene	Unalloyed cast iron
Ethylene oxide	Unalloyed cast iron
Monochloroethylene, dry	Unalloyed cast iron
Dichloroethylene, dry	Unalloyed cast iron
Dichloroethylene, damp	15% Si cast iron
Oxygen	'Ni-Resist' cast iron

### Glossary

**Aging** A heat treatment process whereby an alloy, that has been previously quenched in order to retain alloying additions in solid solution, is reheated into a temperature range in which the rate of solid state diffusion is sufficient to permit the precipitation of strengthening second phase particles.

**Maraging steel** An ultrahigh strength low-carbon iron–nickel alloy that is strengthened by the precipitation of second phase intermetallic compounds rather than carbides.

**U-bend** A form of corrosion test specimen that is prepared in the shape of a ‘U’ and commonly used to determine the resistance of a material to SCC.

## Abbreviations

**AISI** American Iron and Steel Industry

## Symbols

$a_{cr}$  Critical crack length for propagation of stress corrosion crack

$K_{ISCC}$  Critical stress intensity threshold for the onset of stress corrosion cracking

### 3.03.1 Introduction

Alloys of iron with nickel have a number of important applications. The first class are of interest due to their unique magnetic characteristics and their abnormally low thermal expansion coefficients in the compositional region of Fe–36%Ni. Although not specifically used as corrosion-resistant materials, their high resistance to attack from many common environments is of benefit in their specialized applications. The second important class, ‘maraging steels,’ are ultra-high strength low-carbon iron–nickel alloys that derive their outstanding mechanical properties from the precipitation of second phase intermetallic compounds rather than carbides.

### 3.03.2 Iron–Nickel Alloys

#### 3.03.2.1 Electrochemistry

The potentiodynamic polarization curves of Beauchamp, [Figure 1](#), demonstrate the effect of increasing nickel content on the anodic behavior of iron–nickel alloys in 0.5 M H<sub>2</sub>SO<sub>4</sub>. The maximum current in the active region is reduced and the potentials moved to more noble values; the current in the passive region is increased and some evidence of secondary passivity appears. The greater nobility with increasing nickel content in the active region is of importance in acid environments where hydrogen evolution is the major cathodic reaction, and results in significantly lower rates of corrosion. In neutral environments, the protection provided by a layer of insoluble corrosion products is of greater significance.

#### 3.03.2.2 Atmospheric Corrosion

The addition of small amounts of nickel to iron improves its resistance to corrosion in industrial

**Figure 1** Effect of nickel on the anodic behavior of iron alloys in 1 M H<sub>2</sub>SO<sub>4</sub> at 25 °C. Curve 1 – Fe; Curve 2 – Fe–10Ni; Curve 3 – Fe–36Ni; Curve 4 – Ni. Reproduced from Beauchamp, R. L. Dissertation, Ohio State University, 1966; Figure 27.

atmospheres due to the formation of a protective layer of corrosion products. Larger additions of nickel, for example, 36% or 42%, are not all that beneficial with respect to overall corrosion, since the rust formed is powdery, loose, and nonprotective, leading to a linear rate of attack as measured by weight loss. [Figure 2](#) of Pettibone<sup>2</sup> illustrates the results obtained.

With respect to resistance to pitting corrosion, there is an increasing advantage to be obtained by increasing the nickel content up to 50%. There is little distinction between the Fe–50Ni alloy and pure nickel. Data on the corrosion of Fe–36Ni alloy at an industrial site in the United States are reported by La Que and Copson<sup>3</sup> and at a European site by Evans.<sup>4</sup> In marine atmospheres, the overall rates of corrosion are reduced progressively with increase in nickel content up to 35%, but with small improvement thereafter. The rates of corrosion at various sites, reported by Friend,<sup>5</sup> show the superiority of Fe–36Ni over mild steel with respect to both average and localized corrosion ([Table 1](#)).

### 3.03.2.3 Corrosion in Natural Environments

#### 3.03.2.3.1 Seawater

The average rates of corrosion of Fe–36Ni alloy exposed to alternate immersion in seawater are appreciably greater than those that occur when the

**Figure 2** Resistance of nickel–iron alloys to corrosion by an industrial atmosphere in Bayonne NJ, USA. Reproduced from La Que, F. L.; Copson, H. R., Ed. *Corrosion Resistance of Metals and Alloys*, 2nd ed.; Reinhold Publishing Corporation/Van Nostrand Reinhold Ltd: New York/London, 1963; p 458.

alloy is exposed to marine atmospheres. Although the rates of corrosion are significantly below those observed for mild steel (Table 2), the superiority over mild steel is not all that great with respect to pitting attack.

Nickel–iron alloys fully immersed in seawater may suffer localized corrosion, which can be severe under conditions where oxygen is constantly renewed at the surface and the formation of protective corrosion products is hindered, for example, in fully-aerated flowing seawater. In quieter, less oxygenated conditions, average corrosion rates of Fe–36Ni are low and well below those for mild steel, as exemplified in the data given in Table 3. However, the resistance to localized attack is not improved to the same extent.

#### 3.03.2.3.2 Freshwater

Nickel–iron alloys suffer significantly less corrosion than mild steel when exposed to a soft, freshwater, but Friend<sup>5</sup> found that the resistance to pitting is only slightly greater. For example, the average corrosion rate for mild steel after 15 years' exposure was  $0.94 \text{ g m}^{-2} \text{ day}^{-1}$  as against  $0.07 \text{ g m}^{-2} \text{ day}^{-1}$  for Fe–36Ni. On the other hand, the maximum pit depths were similar, 2.2 and 2.0 mm for mild steel and Fe–36Ni respectively.

**Table 1** Resistance of Fe–36Ni and mild steel to corrosion in marine atmospheres<sup>5</sup>

Location	Corrosion after exposure for 15 years			
	Average ( $\text{g m}^{-2} \text{ day}^{-1}$ )		Localized (max. pit depth, mm)

### 3.03.2.4 Corrosion in Industrial Environments

#### 3.03.2.4.1 Acids

Much of the information available on the resistance of nickel-iron alloys to corrosion by mineral acids is summarized by Marsh.<sup>6</sup> In general, corrosion rates decrease sharply as the nickel content is increased from 0 to 30–40%, with little further improvement above this level. The value of the nickel addition is most pronounced in conditions where hydrogen evolution is the major cathodic reaction, that is, under conditions of low aeration and agitation. Results reported by Hatfield<sup>7,8</sup> show that the rates of attack of Fe–25Ni alloy in sulfuric and hydrochloric acid solutions, although much lower than those of mild steel, are still appreciable (Table 4). In solutions of nitric acid, nickel-iron alloys show very high rates of corrosion.

Bourelrier *et al.*<sup>9</sup> and Raicheff *et al.*<sup>10</sup> investigated the inhibitive effect of chloride ions on corrosion in sulfuric acid. The inhibition efficiency was found to depend on the alloy composition, alloy surface, and chloride concentration. The more aggressive the environment, the greater the inhibition efficiency. Yagupol'skaya *et al.*<sup>11</sup> studied the effect of iodine

additions to sulfuric acid on the corrosion resistance of Ni and Ni–Fe alloys. Again there was an inhibitive effect caused by the halide ion. Uto *et al.*<sup>12</sup> studied Ni–Fe–Si alloys, adding Si to improve the castability of the simple Ni–Fe materials. They found that alloys containing 0–70% Fe and 5–10% Si, with the balance being Ni, are usable in 0–85% sulfuric acid at temperatures of up to 80 °C and in 0–10% hydrochloric acid at temperatures of up to 40 °C.

Cid *et al.*<sup>23</sup> studied the corrosion resistance of Ni, 5% Fe–Ni and 10% Fe–Ni alloys in the transpassive region in sulfuric acid. For a given acid concentration, the addition of iron reduced the corrosion rate. It was concluded that the addition of small percentages of Fe was doubly beneficial, decreasing both general and intergranular corrosion.

#### 3.03.2.4.2 Salt solutions

Nickel-iron alloys are more resistant than iron to attack by solutions of various salts. In alternate immersion tests in 5% sodium chloride solution, Fink and De Croly<sup>13</sup> determined values of 2.8, 0.25, and 0.5 g m<sup>−2</sup> day<sup>−1</sup> for alloys containing 37%, 80%, and 100% nickel as against 46 g m<sup>−2</sup> day<sup>−1</sup> for iron. Corrosion rates of about 0.4 g m<sup>−2</sup> day<sup>−1</sup> are reported by Hatfield<sup>7</sup> for Fe–30Ni alloy exposed to solutions containing 5% magnesium

**Table 3** Resistance of Fe–36Ni alloy and mild steel to corrosion when fully immersed in seawater<sup>5</sup>

Location	Corrosion after exposure for 15 years			
	Average (g m <sup>−2</sup> day <sup>−1</sup> )		Localized (max. pit depth, mm)	
	Fe–36Ni	Mild steel	Fe–36Ni	Mild steel

	5% HCl			25% HCl		
	15 °C	40 °C	60 °C	15 °C	40 °C	60 °C
Carbon steel	23	40	41	63	188	185
Fe–25Ni	0.45	2.3	5.4	0.9	0.9	19

sulfate, 10% magnesium chloride, and 10% sodium sulfate; the same alloy corroded at a rate of about  $1.2 \text{ g m}^{-2} \text{ day}^{-1}$  in 5% ammonium chloride.

In a study of the corrosion of 10 binary nickel–iron alloys in 3% sodium chloride solution, Schwerdtfeger<sup>14</sup> found the average corrosion rate to decrease from  $1.4\text{--}1.6 \text{ g m}^{-2} \text{ day}^{-1}$  for alloys containing 0–16% nickel alloy to  $0.1 \text{ g m}^{-2} \text{ day}^{-1}$  for a 57% nickel–iron alloy. There was little further reduction in the rate of weight loss for the higher-nickel alloys. However, the alloys showed an increasing tendency to suffer pitting and crevice corrosion with increasing nickel content.

### 3.03.2.4.3 Stress corrosion

In tests lasting for 14 days, Copson<sup>15</sup> found that the susceptibility of steel to stress corrosion cracking (SCC) in hot caustic soda solutions increased with increase in the nickel content up to at least 8.5%. Alloys containing 28% and more of nickel did not fail in this period. In boiling 42% magnesium chloride, the 9% nickel–iron alloy was the most susceptible of those tested to cracking (Table 5) with alloys containing 28 and 42% nickel not failing within 7 days. Couper<sup>16</sup> reports cracking of an Fe–36Ni alloy in 10–55 days in this medium. Radd *et al.*<sup>17</sup> have noted cracking of Fe–36Ni alloys at ambient temperatures in an unspecified environment, but this possibly may have been residual traces of acid copper chloride etching solution.

Marquez *et al.*<sup>18</sup> studied the effect of cold rolling on the resistance of Ni–Fe alloys to hydrogen cracking. It was found that low-carbon, 10–19% Ni–Fe alloys become considerably more resistant to hydrogen cracking after severe cold rolling. The observed resistance decreased with increasing carbon content and the improvement was directional, the optimum effect applying to specimens stressed in the longitudinal direction.

### 3.03.2.4.4 Galvanic corrosion

Galvanic corrosion of nickel–iron alloys may be of significance in welding operations. Ni–45Fe alloys are used as filler materials in the welding of cast irons but the favorable area relationship of weld metal to base plate mitigates the effect of the more noble characteristics of the nickel–iron alloy. Thus, their application in corrosive environments is rarely of concern.

Of more serious practical significance is iron contamination of nickel-clad steel welds. Tables 6 and 7 show the increase in corrosion of various nickel–iron alloys that may occur when coupled to nickel in calcium chloride or sodium hydroxide solutions. It is evident that in the calcium chloride solution, 5% iron contamination of weld metal can be tolerated, while in the sodium hydroxide solution bimetallic corrosion will not become significant until contamination exceeds 20%.

## 3.03.3 Maraging Steels

### 3.03.3.1 Composition

Notwithstanding their name, maraging steels are a class of high-strength iron alloys of very low carbon content. Strengthening is achieved by the use of substitutional alloying additions that result in the precipitation of secondary phases during age hardening of a quenched martensitic iron–nickel matrix. The term maraging was thus coined from the words ‘martensite’ and ‘age hardening.’

The development of maraging steels began in the late 1950s, on steels containing 20 and 25% Ni using a combination of aluminum, titanium, and niobium as age-hardening elements.<sup>19</sup> Later work<sup>20</sup> revealed the important synergistic age-hardening effect of cobalt plus molybdenum and led to the development of the 18% Ni maraging steels. Using titanium as a

**Table 5** Resistance of iron–nickel alloys to SCC in boiling 42% magnesium chloride

Composition of alloy					Hardness	Time to cracking (days)	Comments

supplementary hardening element, and with appropriate balancing of cobalt and molybdenum, nominal yield strengths in the range of 1370–2400 MPa can readily be achieved. **Table 8** lists the nominal composition of the 18% Ni maraging steels. Other types of maraging steel include an alloy (17% Ni) developed for use as a casting,<sup>21</sup> and a 12Ni–5Cr–3Mo alloy. Stainless-type alloys have also been developed<sup>22</sup> but are outside the scope of this section.

During the 1970s, the price of cobalt increased enormously and then declined. These price fluctuations plus the concern about the future supply of cobalt caused serious declines in the use of the cobalt-containing grades of maraging steel. In response to this market change, a new cobalt-free grade of maraging steel was developed.<sup>23</sup> The composition of this steel is given as 18.5Ni, 3.0Mo, 1.4Ti, and 0.1Al. Its strength is 1720 MPa and its mechanical properties approximate those of the 18% Ni 240 maraging steel. Discussion in this chapter is restricted to the 18% Ni maraging steels.

**Table 6** Bimetallic corrosion between nickel and nickel–iron alloys in 16% calcium chloride solution<sup>2</sup>

Ni–20Fe	1.0	0.044

<sup>a</sup>Room temperature test of duration 120 days, solution agitated. Cathode:anode area = 100:1.

### 3.03.3.2 Structural Features

On cooling to room temperature after annealing, maraging steels transform completely to martensite. The as-annealed structure consists of packets of parallel lath-like martensite platelets arranged within a network of prior austenite grain boundaries. The platelets have a high dislocation density but are not twinned.

On heat treating at 485 °C, a very rapid age-hardening reaction takes place and greatly strengthens the material. Although the nature of the precipitates formed is still uncertain, the consensus of opinion is that ageing for several hours at 485 °C results in a Ni<sub>3</sub>Mo phase, while longer times produce the Fe<sub>2</sub>Mo phase. There may also be a titanium precipitate, η-Ni<sub>3</sub>Ti or Ni<sub>3</sub>(Mo,Ti)<sub>3</sub>. Ageing at higher temperatures or longer times results in some reversion to austenite, which may be stable at room temperature (depending on time and temperature of ageing), and to a lower strength.

### 3.03.3.3 Physical and Mechanical Properties

Summaries of the physical and mechanical properties of the 18% Ni maraging steels are given in **Tables 9** and **10**. The mechanical properties are highlighted by good ductility, toughness, and a lack of notch sensitivity. The plane strain fracture toughness of maraging steels is superior to other alloys at comparable strength levels (**Table 11**).

### 3.03.3.4 Fabrication

Maraging steels have been produced by both air and vacuum melting. Small amounts of impurities can

Lattice parameter	Martensite 2.856–2.862 Å at room temperature; austenite (retained) 3.58 Å
Thermal conductivity	19.68–20.93 kW m <sup>-2</sup> °C (20–100 °C)
Electrical resistivity	60–70 μΩ cm when solution annealed at 815 °C; 35–50 μΩ cm when maraged at 485 °C for 3 h
Melting temperature	1430–1445 °C
Transformation temperature	M 145–200 °C; M 77–145 °C; A 445 °C
Nominal length change	–0.06% to –0.10% during maraging

decrease toughness significantly. Sulfur in particular is detrimental and should be kept as low as possible. Silicon and manganese also have a detrimental effect on toughness and should be maintained below a combined level of 0.20%. Such elements as C, P, Bi, O, N, and H should be kept to the lowest levels practicable.

The maraging steels are readily hot worked by conventional rolling and forging operations. A preliminary homogenization at 1210–1260 °C is normally used prior to hot working at that temperature. During subsequent hot working, extended times at, or slow cooling through, temperatures from 760 to 1100 °C should be avoided, since they produce embrittlement.<sup>25</sup> Maraging steels can be cold worked up to 85% before requiring intermediate annealing (because of low work-hardening characteristics) but are usually annealed after smaller reductions.

Heat treatments are relatively simple and normally consist of annealing for 1 h at 815 °C followed by ageing for 3 h at 485 °C. Recently, double annealing treatments have grown in favor. Machining or fabrication is easily performed in the as-annealed condition. Subsequent age hardening generally introduces small and predictable dimensional changes.

### 3.03.3.5 Corrosion of Maraging Steels

#### 3.03.3.5.1 Natural environments

In atmospheric exposure, 18% Ni maraging steel corrodes in a uniform manner<sup>22</sup> and becomes completely rust covered. Pit depths tend to be less deep than for low-alloy high-strength steels.<sup>26</sup> Atmospheric corrosion rates<sup>27</sup> in industrial (Bayonne, NJ) and marine (Kure Beach, NC) atmospheres are compared with those for low-alloy steel in **Figures 3** and **4** respectively. The corrosion rates drop substantially after the first year or two, and in all cases, the rates for maraging steel are about half the corrosion rate for HY80 and AISI 4340 steels.

The corrosion rates for both maraging steel and the low-alloy steels in seawater are similar initially, but from about 1 year onwards, the maraging steels tend to corrode more slowly as indicated in **Figure 5**. The corrosion rates for both low alloy and maraging steel increase with water velocity.<sup>5</sup> During seawater exposure, the initial attack was confined to local anodic areas, whereas other areas (cathodic) remained almost free from attack; the latter were covered with a calcareous deposit typical of cathodic areas in seawater exposure. In time, the anodic rust areas covered the entire surface.<sup>6</sup>

Polarization tests<sup>27</sup> indicate that maraging steel does not exhibit passive behavior in 3% NaCl, and that the polarization curves are unaffected by changes in heat treatment.

#### 3.03.3.5.2 Industrial environments

The corrosion rates of maraging steels in acid solutions such as sulfuric, hydrochloric, formic, and stearic acids are substantial, although lower than those of the low-alloy high-strength steels.<sup>28</sup> Polarization studies<sup>29</sup> indicate that maraging steels exhibit active-passive behavior in 1 and 0.1 M sulfuric acid. The corrosion potential, critical current density, primary passivation potential, and passive current density are all affected by variations in ageing treatment.

**Table 10** Summary of nominal mechanical properties for the 18% Ni maraging alloys

Property	18% Ni 200	18% Ni 250	18% Ni 300	18% Ni 350
Yield strength –0.2% offset ( $\text{MN m}^{-2}$ )	1310–1550	1650–1820	1780–2060	2270–2480
Ultimate tensile strength ( $\text{MN m}^{-2}$ )	1340–1580	1680–1860	1820–2100	2300–2510
Elongation in 25.4 mm (1 in.), (%)	11–15	10–12	7–11	6–10
Reduction in area (%)	35–67	35–60	30–50	25–45
Modulus of elasticity $E$ ( $\text{kN m}^{-2}$ )	$18.0 \times 10^7$	$18.5 \times 10^7$	$18.9 \times 10^7$	$19.3 \times 10^7$
Hardness (Rockwell C)	44–48	48–50	51–55	56–59
Impact Charpy V-notch (J)	35–68	24–45	16–26	7–14
Notch tensile				
0.0128 m bar $K_1 = 10$ ( $\text{MN m}^{-2}$ )	2390	2350–2510	2900–3100	–
0.00762 m bar $K_1 = 10$ ( $\text{MN m}^{-2}$ )	–	2560–2660	–	1360–1490
Fracture toughness ( $K_{Ic}$ ) ( $\text{MN m}^{-2}$ )	101–176	98–165	88–143	44–82
Endurance limit ( $\text{MN m}^{-2}$ )				
Smooth bar $10^8$ cycles	620–795	620–760	760–900	690
Notched bar $10^8$ cycles ( $K_t = 2.2$ )	275–345	275–380	275–415	–
( $K_t = 2.8$ )	–	–	–	352

In all cases treatment was for 1 h at 815 °C plus 3 h at 485 °C.

**Table 11** Comparison of toughness of maraging steels and other high strength alloys

Alloy	Yield strength ( $\text{MN m}^{-2}$ )	$K_{Ic}$ ( $\text{MN m}^{-2} \sqrt{\text{m}}$ )

Source:  $K_{Ic}$  is the plane strain fracture toughness (see Section 8.9). Bourelle, F., Vu Quang, K. In Proceedings of the Conference, 10th International Congress Metallic Corrosion, Madras, India, November 1987, 1988; p 2813.

Data Bulletin on 18% Ni Maraging Steels, The International Nickel Company, Inc. 1964.

The critical and passive current densities increase as the structure is varied from fully annealed to fully aged. The normal heat treatment produces critical and passive current densities of 0.4 and 0.2  $\text{mA cm}^{-2}$  respectively ( $0.1 \text{ mA cm}^{-2} \sim 1.2 \text{ mm year}^{-1}$ ).<sup>30</sup>

### 3.03.3.6 Stress Corrosion Cracking

#### 3.03.3.6.1 Mechanisms

The 18% Ni maraging steels do not display passivity and normally undergo uniform surface attack.

Of more serious consequence, however, for all high strength steels, is the degree of susceptibility to SCC. For high-strength steels in general, the stress corrosion process in aqueous media is characterized by delayed failure, which consists of an incubation period followed by slow, and at times, intermittent crack growth. Failure can occur on loading to some fraction of the yield stress or through the action of residual stresses, often in environments as mild as humid air.<sup>31</sup> The degree of susceptibility depends on the mode of loading and is highest in cases of plane strain loading (triaxial stresses), with tensile loading and plane stress bending, in that order, representing less severe loading conditions<sup>32</sup> (tensile stresses of course are present in all these modes of loading). In general, susceptibility to SCC increases with increasing yield strength. Different alloy types, however, vary in their degree of resistance, and at comparable strength levels, maraging steels compare favorably in cracking resistance with other high-strength steels.

For a variety of steels, including maraging steels, it was found that under freely corroding conditions, the pH of the solution near the crack tip was about 3.8 for the materials studied.<sup>33</sup> Furthermore, potential measurements indicated that thermodynamic conditions were satisfied for hydrogen ion reduction. Further potential–pH measurements were made on AISI 4340 steel exposed to 0.6 N NaCl solutions of different pH and polarized to potentials both negative and positive with respect to the corrosion potential.<sup>34</sup> It was found that the pH of the solution in the crack was determined

solely by electrochemical reactions at the crack tip irrespective of starting pH. It was also apparent that, regardless of the impressed potential, the electrochemical conditions in the crack satisfied the thermodynamic requirements for the production of hydrogen. These results indicate that it is not necessary to invoke an active path mechanism and that hydrogen is available even during anodic polarization of AISI 4340 steel.

Activation energy measurements for SCC of H-11 steel and AISI 4340 in water and moist air are

**Figure 3** Corrosion rates of maraging and low alloy steels in an industrial atmosphere at Bayonne NJ, USA. Reproduced from Kenyon, N.; Kirk, W. W.; van Rooyen, D. *Corrosion* **1971**, 27, 390.

**Figure 4** Corrosion rates of maraging and low alloy steels 244 m from the sea at Kure Beach NC, USA. Reproduced from Kenyon, N.; Kirk, W. W.; van Rooyen, D. *Corrosion* **1971**, 27, 390.

similar<sup>34,35</sup> and suggest that the cracking rate in these alloys is controlled by the diffusion of hydrogen, since these are in close agreement with the value for the diffusion of hydrogen through AISI 4340 membranes.<sup>36</sup> There is little question that at strongly negative potentials, cracking occurs by hydrogen embrittlement. For all other cases, there does not appear to be a strong basis for favoring one mechanism over the other or to discard the possibility that each mechanism shares in the control of the cracking process. The latter possibility for maraging steel has been supported by a study of cracking response to polarization, fractographic studies, and pH determinations of the corrodent at the tip of the crack.<sup>37</sup> Craig and Parkins<sup>38</sup> have shown good evidence that cracking can proceed by hydrogen embrittlement at more negative potentials, by anodic dissolution at more positive potentials, and possibly by combinations of both mechanisms at intermediate potentials. The effects of precracking or pitting of smooth specimens was also examined. In many instances, the local changes in chemistry of the test solution in the cracks or pits was more important than the stress concentrations at these locations.

### 3.03.3.6.2 Testing for SCC

The stress corrosion resistance of maraging steel has been evaluated both by the use of smooth specimens loaded to some fraction of the yield strength and taking the time to failure as an indication of resistance, and by the fracture mechanics approach,<sup>39</sup> which involves the use of specimens with a preexisting crack. Using the latter approach, it is possible to obtain crack propagation rates at known stress intensity factors ( $K$ ) and to

**Figure 5** Corrosion rates of maraging and low alloy steels in seawater flowing at  $0.6 \text{ m s}^{-1}$ . Reproduced from Kenyon, N.; Kirk, W. W.; van Rooyen, D. *Corrosion* **1971**, 27, 390.

determine critical stress intensity factors ( $K_{ISCC}$ ) below which a crack will not propagate.

Any test in which time to failure of smooth specimens is determined is an overall measure of the incubation period to initiate a crack, the ability to resist the propagation of a stress corrosion crack, and the ability to resist final mechanical fracture. Since this test does not indicate the relative merits of an alloy in each individual aspect of the cracking process, it is probably of less benefit to a design engineer. The use of precracked specimens in the fracture mechanics approach follows from the philosophy that structures are likely to contain crack-like defects. The use of precracked specimens promotes a rapid change in the chemistry of the solution at the crack tip and shortens or eliminates the initiation time for crack propagation.

### 3.03.3.6.3 Cracking resistance in smooth materials

Maraging steel in the strength range 1240–1720 MPa tested as U-bends in seawater displayed good resistance, as it did not fracture in periods of up to 2–3 years although there was considerable general corrosion and fouling. However, microcracks were observed after 6 months. Similar behavior<sup>22,26</sup> of U-bend and bent beam specimens can be expected in industrial or marine atmospheres, although general corrosion is less severe. By comparison, AISI 4340 at strength levels of 1660 MPa failed in about 1 week in both seawater and atmospheric tests. Maraging steel of yield strength at or above 2060 MPa was not resistant and failed rapidly. Welds in maraging steel are somewhat less resistant than base plate. U-bend exposure of 1240 MPa strength welds survived for up to 2 years in seawater, while at 1380 MPa, failures occurred in 2–18 months.<sup>28</sup>

It is possible to provide cathodic protection to materials of up to 1720 MPa yield strength, by coupling to mild steel or possibly to zinc.<sup>22,26</sup> However, zinc and metals more active than zinc tend to induce hydrogen embrittlement. Welds up to 1380 MPa may be cathodically protected by zinc, but at impressed potentials of  $-1.25$  V (vs. the standard calomel electrode), both 1240 and 1380 MPa welds fail rapidly due to hydrogen embrittlement.<sup>28</sup> Hence, although tests on smooth specimens indicate that cathodic protection of maraging steel is possible, tests on specimens with preexisting cracks indicate a greater sensitivity to hydrogen embrittlement during cathodic polarization.<sup>28</sup> The use of cathodic protection on actual structures must therefore be applied with caution, and the application of less negative potentials than are

indicated to be feasible in smooth specimen tests is to be recommended if it is assumed that structures contain crack-like defects. Further evidence of the relative resistance of maraging steel is reproduced in Figure 6. Also shown is the beneficial effect in smooth surface tests of cold rolling; shot peening has a similar beneficial effect.<sup>28</sup>

### 3.03.3.6.4 Critical stress intensity factor

It has become common to use  $K_{ISCC}$ , the critical stress intensity factor, as a measure of the resistance of an alloy to SCC. Tests are performed on specimens that are precracked by a fatigue machine and must be of sufficient dimensions to ensure plane strain conditions. Figure 7 presents a summary comparing the  $K_{ISCC}$  values of maraging steel, with values for H-11, AISI 4340, AM 355, AISI410, 17–4 PH, 13–8 Mo PH, D6AC, and 9Ni–4Co–C steels. The data have been taken from a number of sources<sup>28,40–43</sup> and are for exposures in aqueous environments, with and without NaCl. No attempt has been made to distinguish between different environments, since they do not affect the results appreciably.

Plotted points marked W in Figure 7 refer to data for welds; also included are lines of critical crack depth  $a_{cr}$ . The region below a line of specified critical crack depth corresponds to combinations of strength and  $K_{ISCC}$  for which a long crack of the specified depth will propagate when stressed to the yield point, whereas the region above the line corresponds

**Figure 6** Bent-beam test results in aerated distilled water. These specimens were exposed to the environment at a stress of 70% of yield. Reproduced from Setterlund, R. B. *Mater. Protect.* **1965**, 4(12), 27.

**Figure 7** Comparison of  $K_{ISCC}$  as a function of yield strength of 18% Ni maraging and other high strength steels.

to the strength and  $K_{ISCC}$  combinations for which the crack will not propagate. The critical crack depth (assuming yield point stresses) for cracks the length of which greatly exceeds their depth is given by:

$$a_{cr} = 0.2 \left( \frac{K_{ISCC}}{\sigma_y} \right)^2$$

where  $\sigma_y$  is the yield stress.<sup>44</sup>

In general, it is clear that maraging steels compare favorably with other high-strength steels and offer comparatively high  $K_{ISCC}$  values over a wide range of strength. It is also clear that maraging steels can withstand a greater crack depth without crack propagation.

A further estimation of the corrosion resistance of maraging steel can be obtained from data on the rate of crack propagation. Although the rate of crack propagation has been found to be a function of stress intensity in some alloys, for many alloys and heat treatments, there is a range of stress intensity above  $K_{ISCC}$  and approaching  $K_{IC}$  at which the rate of crack propagation is independent of stress intensity (Table 12).<sup>45</sup> The cracking rate for maraging steel is seen to be slower than for 4340 and D6AC and equivalent to H-11 and HP 9Ni-Co-C steels, at a strain rate of  $10^{-5} \text{ mm s}^{-1}$ . The fact that cracks propagate very slowly in maraging steels has an important consequence related to their stress corrosion testing.

**Table 12** Crack propagation rates for a number of high strength steels

Alloy	Yield strength ( $\text{MN m}^{-2}$ )	Crack velocity ( $\text{mm s}^{-1}$ )
Maraging 250	1570	$1.31 \times 10^{-5}$
Maraging 250	1690	$1.40 \times 10^{-5}$
Maraging 300	1950	$2.75 \times 10^{-4}$
Modified maraging 300 <sup>a</sup>	2180	$1.18 \times 10^{-4}$
Modified maraging 300 <sup>a</sup> (underaged)	1810	$0.72 \times 10^{-3}$
Modified maraging 300 <sup>a</sup> (overaged)	1760	$2.88 \times 10^{-5}$
4340	1430	$1.65 \times 10^{-3}$
D6AC	1540	$1.74 \times 10^{-4}$
H-11	1420	$1.19 \times 10^{-5}$
HP 9-4-25	1330	$2.54 \times 10^{-5}$
HP 9-4-45 (bainitic)	1460	$1.06 \times 10^{-5}$

Source: Carter, C. S. *Met. Trans.* 1970, 1, 1551.

<sup>a</sup>No details on the modification were available.

In determining  $K_{ISCC}$  by dead-weight loaded cantilever beam tests, it has been recommended<sup>46</sup> that maraging steel should withstand 1000 h without failure to ensure that the applied stress intensity is at, or lower than,  $K_{ISCC}$ .

### 3.03.3.6.5 Effect of metallurgical variables on SCC

It is notable that while it is possible to produce maraging steels with consistently uniform mechanical properties, the stress corrosion properties are subject to scatter, as indicated in Figure 7. To a large extent, this scatter is an indication of the greater sensitivity of SCC to metallurgical variables. Although the variation in cracking resistance is not well understood, and the reaction to certain treatments not always consistent, certain observations may be used to indicate guidelines for improved properties. Cracking in maraging steels has generally been observed to be intergranular with isolated cases of transgranular cracking.<sup>26,47,48</sup> Both  $\text{Ti}_2\text{S}$  and  $\text{Ti}(\text{C},\text{N})$  on prior austenite boundaries have been suggested to be related to greater susceptibility. Thus, since prolonged time in the temperature range 760–1100 °C favors the precipitation of  $\text{Ti}_2\text{S}$  and  $\text{Ti}(\text{C},\text{N})$  on prior austenite boundaries, such exposures should be avoided both in processing and in annealing.

Studies of the effect of ageing temperature on cracking behavior have shown rather marked effects. Under-ageing at temperatures of 455 °C or lower was found to increase greatly the rate of crack propagation without affecting the mode of crack propagation

**Figure 8** Oxidation rate at 535 °C of 18Ni250 maraging steel compared with a generally-available tool steel. These tests were performed on 6.35 mm cubes exposed to still air for 5, 25, and 100 h. The weight gain includes the scale formed during heating and cooling. Reproduced from Data Bulletin on 18% Ni Maraging Steels, The International Nickel Company, Inc. 1964.

(intergranular) or  $K_{\text{ISCC}}$ .<sup>45,47,49</sup> However, over-ageing appears to offer slightly slower crack growth rates (Table 12), but it did not significantly improve  $K_{\text{ISCC}}$ .<sup>29</sup> The best combination of properties is obtained with the normal ageing treatment at 485 °C.

Studies on welds showed that cracking resistance as indicated in U-bend tests<sup>28</sup> was substantially increased by a postweld anneal (1 h at 815 °C) prior to the normal ageing treatment. Material aged in the as-welded condition was less resistant. The most significant structural difference resulting from the two heat treatments was a finer dispersion of austenite ribbons in material annealed before ageing.

### 3.03.3.7 High Temperature Corrosion

Little data are available on hot corrosion behavior. Figure 8 indicates maraging steel to have better resistance to air exposure at 535 °C than a 5% Cr tool steel.<sup>24</sup> Metallographic examination indicates that exposure to air at elevated temperatures results in reaction with both oxygen and nitrogen, forming both oxides and titanium carbonitrides. Under some conditions of reduced oxygen partial pressure, selective subsurface oxidation of iron can occur.

### 3.03.3.8 Applications

Maraging steels have found varied uses in the aerospace and aircraft industries. These uses have included rocket motor cases, landing gear components, aircraft forgings and fasteners. Other areas of usage include machine tool and die applications, and extrusion hardware. Marine uses include hydrofoil foil systems and aircraft arrester hooks.

## Glossary

**Active** Describes a metal which corrodes in the negative direction of electrode potential.

**Activation polarization** Corrosion reaction determined kinetically by the participating electrode reactions.

**Anaerobic** Free of air or oxygen.

**Anode** The electrode of an electrolyte cell at which oxidation occurs.

**Anodic polarization** The change in the electrode potential in the noble positive direction.

**Austenite** A face-centered cubic crystalline phase of iron-base alloy.

**Cathode** The electrode of an electrolytic cell at which reduction is the principal reaction.

**Cathodic polarization** The change of the electrode potential in the active negative direction.

**Cathodic protection** Reduction of corrosion rate by shifting the corrosion potential of the electrode towards a less oxidizing potential by applying an external electromotive force.

**Cold work** The operation of shaping metals at temperatures below their recrystallization temperatures so as to produce strain-hardening.

**Corrosion – fatigue** Fatigue type cracking of metal caused by repeated or fluctuating stresses in a corrosive environment.

**Corrosion potential,  $E_{\text{corr}}$**  The potential of a corroding surface in an electrolyte, relative to a reference electrode, also called open circuit potential.

**Double layer** The interface between an electrode or a suspended particle and an electrolyte created by charge-charge interaction leading to an alignment of oppositely charged ions at the surface of the electrode or particle.

**Ductility** Ability of materials to be deformed by working process and to retain strength and freedom from cracks when their shape is altered.

**Electrolyte** A chemical substance or mixture, usually liquid, containing ions that migrate in an electric field.

**Elongation** The percentage plastic extension produced in a tensile test.

**Embrittlement** Loss of ductility of a material resulting from a chemical or physical change.

**Equilibrium potential** The potential of an electrode in an electrolytic solution when the forward

rate of a given reaction is exactly equal to the reverse rate.

**Erosion** Destruction of materials by abrasive action of moving fluids, usually accelerated by the presence of solid particles.

**Fatigue** The phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the tensile strength of the material.

**Ferrite** A body-centered cubic crystalline phase of iron-base alloys.

**Galvanic corrosion** Corrosion associated with the current resulting from the electrical coupling of dissimilar electrodes in an electrolyte.

**General corrosion** A form of deterioration that is distributed more or less uniformly over a surface.

**Hardening** The process of making steel hard by cooling from above the critical range at a rate that prevents the formation of ferrite and pearlite and results in the formation of martensite.

**Heat affected zone (HAZ)** That portion of the base metal that was not melted by welding but whose microstructure and properties were altered by the heat of the welding process.

**Inclusion** A nonmetallic phase such as an oxide, sulfide or silicate particle in a metal.

**Martensite** Metastable body-centered phase of iron super-saturated with carbon, produced from austenite by shear transformation during quenching or deformation.

**Mixed potential** A potential resulting from two or more electrochemical reactions occurring simultaneously on one metal surface.

**Noble** The positive direction of electrode potential.

**Open circuit potential** The potential of an electrode measured with respect to a reference electrode when no current flows to or from it (see also corrosion potential).

**Passivation** A reduction of the anodic reaction rate of a metal.

**Passive** A metal corroding under the control of a surface reaction product.

**Passivity** The state of being passive.

**Pits, pitting** Localized corrosion of a metal surface that is confined to a small area and takes the form of cavities.

**Polarization** The deviation from the open circuit potential of an electrode.

**Polarization curve or polarization diagram** A plot of current density versus electrode potential for a specific electrode-electrolyte combination.

**Potentiodynamic** The technique for varying the potential of an electrode in a continuous manner at a present rate.

**Potentiostat** An instrument for automatically maintaining an electrode at a constant potential or controlled potential with respect to a reference electrode.

**Potentiostatic** The technique for maintaining a constant electrode potential.

**Precipitation hardening** Improving the strength of solid solution alloys by controlling the formation of precipitates on a crystal lattice scale.

**Reference electrode** A reversible electrode used for measuring the potentials of other electrodes.

**Relative humidity, RH** The ratio, expressed as a percentage, of the amount of water vapor present in a given volume of air at a given temperature to the amount required to saturate the air at that temperature.

**Scanning electron microscope (SEM)** An electron optical device that images topographical details with maximum contrast and depth of field by the detection, amplification and display of secondary electrons.

**Sensitizing heat treatment** A heat treatment, which causes precipitation of constituents at grain boundaries.

**Solution heat treatment** Heating a metal to a suitable temperature and holding at that temperature long enough for one or more constituents to enter into solid solution, then cooling rapidly enough to retain the constituents in solution.

**Tempering** The reheating of hardened steel at any temperature below the critical range, in order to decrease the hardness. Sometimes drawing.

**Toughness** Condition intermediate between brittleness and softness, as indicated in tensile tests by high ultimate tensile stress and low to moderate elongation and reduction in area, or by high values of energy absorbed by impact tests. More precisely it

is the value of the critical strain energy release rate.

**Transpassive** The noble region of potential where an electrode exhibits a current density higher than passive current density.

## Abbreviations

**BCC** Body centered cubic structure  
**CCT** Critical crevice corrosion temperature ( $^{\circ}\text{C}$ )  
**CPT** Critical pitting temperature ( $^{\circ}\text{C}$ )  
**FCC** Face centered cubic structure  
**GS** Grain size  
**HISC** Hydrogen-induced stress cracking  
**LT-MED** Low temperature multi effect, desalination plant  
**Me** Metal  
**MIC** Microbially influenced corrosion  
**MIG** Gas metal arc welding  
**MSF** Multistage flash  
**OCP** Open circuit potential (V)  
**PRE** Pitting resistance equivalent  
**REM** Rare earth metals  
**RH** Relative humidity (%)  
**RO** Reverse osmosis  
**RT** Room temperature  
**SCC** Stress corrosion cracking  
**SCE** Saturated calomel electrode  
**SEM** Scanning electron microscope  
**SHE** Standard hydrogen electrode  
**SSC** Sulfide stress cracking  
**SWRO** Seawater reverse osmosis  
**TIG** Gas tungsten welding  
**TTS** Time temperature sensitization  
**WPA** Wet process phosphoric acid

## Symbols

$\alpha$  Body centered cubic ferrite rich in iron  
 $\alpha'$  Body centered cubic ferrite rich in chromium  
 $A_5$  Elongation or permanent extension of the gauge length after fracture, as expressed as a percentage of the original gauge length.  
 $b_a$  Anodic Tafel slope  
 $C_s$  Concentration of metal ion  
 $\delta$  Diffusion length (m)  
 $D$  Diffusion coefficient of component  $i$  ( $\text{m}^2 \text{s}^{-1}$ )  
 $E$  Potential (V)  
 $E_r$  Transition potential (V)

$E_{\text{corr}}$  Corrosion potential (V)  
 $E_p$  Pitting Potential (V)  
 $E_{pp}$  Passivation Potential (V)  
 $E_{rp}$  Repassivation Potential (V)  
 $E_{tr}$  Transpassive Potential (V)  
 $F$  Faraday's constant ( $\text{A s mol}^{-1}$ )  
 $I$  Current (A)  
 $I_{\text{crit}}$  Critical current density for passivation ( $\text{A cm}^{-2}$ )  
 $i_L$  Anodic limiting current density ( $\text{A cm}^{-2}$ )  
 $K$  Equilibrium constant  
 $K_{\text{ISCC}}$  Threshold stress intensity factor ( $\text{MPa m}^{1/2}$ )  
 $M_{d30}$  The temperature at which martensite will form at a strain of 30%  
 $M_d$  The temperature below where martensite will form  
 $M_s$  Martensite temperature, the starting temperature for martensite transformation  
 $n$  Charge number  
 $N$  Number of cycles  
 $\varphi_s$  Ohmic potential drop in a pit cavity  
 $R$  Stress ratio  
 $R_m$  Tensile strength (MPa)  
 $R_{p0.2}$  Proof strength at which the material undergoes a 0.2% nonproportional (permanent) extension during a tensile test (MPa)  
 $R_{p1.0}$  Proof Strength at which the material undergoes a 1.0% nonproportional (permanent) extension during a tensile test (MPa)  
 $S$  Stress amplitude (MPa)

## 3.04.1 Introduction

The corrosion resistance of stainless steels, in combination with their good mechanical properties and manufacturing characteristics, makes them an extremely valuable and flexible material for designers. Although the usage of stainless steel may have traditionally been relatively low compared with that of carbon steels, growth has been steady, in contrast to the growth of structural steels. The most dominant product form for stainless steels is cold rolled sheet and the major application areas include consumer products and plant and equipment for the oil and gas, chemical process, and food and beverage industries. The most widely used stainless steels are the austenitic grade S30400 and ferritic grades such as S41000, followed by the molybdenum-alloyed austenitic grades, notably S31600.

In terms of their durability and corrosion resistance, iron and most iron-alloyed steels are relatively poor materials, since they easily corrode in air and acid environments unless protected by some external coating and scale in furnace atmospheres. Stainless steels, however, although also belonging to the category of iron-base alloys, offer superior corrosion resistance properties and durability in such diverse environments as seawater, diluted and concentrated acids, and high temperature environments up to 1100°C.

It was the discovery, made about 100 years ago, of the effect of chromium on the resistance of iron in many environments that triggered the development of what is currently the most common group of corrosion-resistant alloys. The first patent for stainless steel was registered in the United Kingdom in 1912 and the development of stainless steels was then sparked off simultaneously in the United Kingdom, the United States, and Germany. Even if most of the stainless steel types currently in use had been available in the 1930s, it was not until the 1960s that developments in process metallurgy gave rise to the growth and widespread use of modern stainless steels.

Early research found that increasing the chromium content of iron to about 10–14% produced a massive drop in corrosion rate in many diverse environments. In time it was also realized that increasing the chromium content above 18–20% improved the corrosion resistance by decreasing the corrosion rate even further. This is the reason that even today many common stainless steel grades contain about 18% chromium. It is the resistance to many common corrosive environments, in combination with good mechanical and fabrication properties, that makes stainless steels universally useful whenever corrosion resistance and long-lasting endurance are required.

### 3.04.2 The use of Stainless Steels

Steel is the predominant metal used in industry. The global production of steel is around 1 billion metric tons a year, of which stainless steel accounts for about 2.5%.

The use and production of stainless steels have for many years been dominated by the industrialized Western nations and Japan, but in recent years, Asian countries, such as India and China, as well as some South American countries, have emerged as important producers and consumers of stainless steels.

The most common product form for stainless steels is cold rolled sheet. Other products, such as

hot rolled plate and sheet, bar, tube and pipe, individually account for only a third or less of the total volumes of cold rolled sheet produced.

The use of stainless steels can be divided into a few major areas, with consumer products, industrial equipment, transport, and construction being the biggest. **Table 1** gives a breakdown of the use of stainless steel by end-user segment.

The most widely used stainless grades are austenitic steels, which typically contain 18% chromium and 8% nickel, that is, S30400/304L. These steels account for more than 50% of the global production of stainless steel. The next most widely used grades are ferritic steels, for example, S41000 (EN 1.4000), followed by molybdenum-alloyed austenitic steels, for example, S31600/316L (EN 1.4401/1.4404). Together, these grades account for over 70% of the total tonnage of stainless steels. However, the use of duplex stainless steels, such as UNS S32205 (EN 1.4462), has been growing considerably recently and this group of stainless steels now accounts for a considerable proportion of the stainless market. The use of duplex grades will certainly increase in future. **Figure 1** shows an

**Table 1** Use of stainless steel divided into application categories

example of the use of a recently developed duplex stainless steel grade, S32101 (1.4162), in a white liquor tank for the pulp- and paper industry.

### 3.04.3 Definition of Stainless Steels, Alloying Elements, and Microstructure

#### 3.04.3.1 Classification of Stainless Steels

Stainless steels are generally defined as iron-based alloys containing at least 10.5% chromium (by weight) and a maximum of 1.2% carbon (by weight). This is the definition given in the European standards. Other definitions may vary slightly, for example, requiring minimum chromium content of 12%, but all definitions agree that stainless steels are iron-based alloys with a substantial amount of chromium, usually in the range of 10.5–12%.

Stainless steels are normally subdivided into five major families or categories based on their crystalline structure and microstructure or hardening mechanism. Each category or family shares a distinct set of general properties, including chemical composition, mechanical properties, fabrication properties, and resistance to certain types of corrosion. Within each of the stainless families there is a considerable range of chemical compositions, and therefore each family consists of several steel grades with variations within the general property profile of the specific category/family.

Stainless steels are divided into different categories according to the three basic microstructures: ferrite, austenite, and martensite. The first two are phases with distinct crystalline structures; ferrite has a body-centered cubic structure and austenite has a face-centered cubic structure. Martensite, on the other hand, is a microstructure that is formed by a complex transformation of an austenitic microstructure under certain conditions. The different

categories of stainless steel are refined further from these basic criteria, either as a single-phase microstructure or as combinations of these structures, to result in five categories of stainless steel, as follows:

- ferritic stainless steels
- austenitic stainless steels
- ferritic–austenitic (duplex) stainless steels
- martensitic stainless steels
- precipitation-hardening (PH) steels

The most common alloying elements used in stainless steels are chromium, nickel, molybdenum, carbon, nitrogen, silicon, and manganese. Silicon and manganese are present in almost all stainless steels in concentrations of 0.2–0.7% and 1–2%, respectively. Other elements are also used for various purposes, but the first five named earlier are the most common alloying elements used to influence the composition of the steel in such a way that the grade falls into a specific category. Different typical combinations of these basic alloying elements are thus characteristic of the different categories of stainless steel, and in [Table 2](#), the typical ranges of the main alloying elements for the different categories of stainless steel are shown.

As can be seen from [Table 2](#), relatively low alloy content characterizes martensitic steels, whereas ferritic steels have high chromium content and no – or virtually no – nickel. This is in contrast to austenitic steels, which always contain nickel and have comparatively high chromium content. Duplex steels fall somewhere in between ferritic and austenitic steels as they typically have high chromium content but less nickel than standard austenitic grades. The use of nitrogen as an alloying element is restricted almost exclusively to austenitic and duplex steels. In some austenitic steel grades, nickel may, to some extent, be replaced by manganese.

**Table 2** Typical ranges for alloying elements in different stainless steel categories

Category	Composition (wt%)					Others
	C	N	Cr	Ni	Mo	
Martensitic	>0.10	–	11–14	0–1	–	
	>0.15	–	16–18	0–2	0–2	
	<0.10	0.05	12–18	4–6	0–2	
Precipitation hardening	0.03–0.20	–	12–17	4–8	0–2	Al, Cu, Ti, Nb, V
	0.05–0.15	–	15–18	4–8	1–3	
Ferritic	<0.08	–	12–27	0–5	0–5	Ti
	<0.25	–	24–28	–	–	
Austenitic	<0.08	0.03–0.7	16–30	8–35	0–7	Cu, Ti, Nb, Mn
Duplex	<0.05	0.05–0.4	18–33	0–7	1–5	Mn

Figures 2 and 3 show examples of a normal microstructure for austenitic and duplex stainless steel.

For commercial stainless steel grades, several international and national standards describe and specify the composition and required properties of stainless steel products. One of the most comprehensive catalogs of steel grades is the Unified Numbering System (UNS). This system does not contain specifications but provides a unified list of alloys that have compositions specified in standards or elsewhere. All stainless steels have the letter 'S' as a prefix in the UNS number. European stainless steel grades are listed along with their compositions in EN 10088-1.<sup>1</sup> American steel grades and their compositions are normally listed in the material and product standards published by ASTM or ASME, for example, ASTM A 240 or ASME SA 240. Table 3 shows the typical chemical composition for a number of commercial stainless steels of various types based mainly on American and European standards.

**Figure 2** Typical microstructure of an austenitic stainless steel.

**Figure 3** Typical microstructure of a duplex stainless steel.

### 3.04.3.2 Alloying Elements and Microstructure

Stainless steels contain a number of different alloying elements, each of which has a specific effect on the properties of the steel. The properties of a specific steel grade will thus be determined by the combined effect of the alloying and trace elements in that specific grade. A brief overview of the alloying elements and their effects on the structure and properties of the steel are given in the following sections together with an explanation of why various elements are added to certain grades.<sup>2</sup> It should also be noted that the effect of the alloying elements differs in some aspects between the hardenable and the nonhardenable stainless steels.

#### 3.04.3.2.1 Chromium (Cr)

This is the most important alloying element as it provides stainless steels with their basic corrosion resistance. Generally speaking, the higher the chromium content, the better the corrosion resistance. Chromium also enhances the steel's resistance to oxidation at high temperatures and promotes a ferritic structure.

#### 3.04.3.2.2 Nickel (Ni)

The main reason for adding nickel is to promote an austenitic structure. Nickel generally increases ductility and toughness. It also lowers the corrosion rate and can thus be used to good effect in acid environments. In precipitation-hardening steels, nickel is also used to form the intermetallic compounds to increase the strength of the steel.

#### 3.04.3.2.3 Molybdenum (Mo)

Molybdenum substantially enhances the resistance to both general and localized corrosion and increases the mechanical strength of steels. In addition to promoting a ferritic structure, molybdenum promotes the formation of secondary phases in ferritic, duplex, and austenitic steels. In martensitic steels, it will increase the hardness at higher tempering temperatures because of its effect on carbide precipitation.

#### 3.04.3.2.4 Copper (Cu)

Copper enhances the corrosion resistance of steels in certain acid environments and promotes an austenitic structure. In precipitation-hardening steels, copper is used to form the intermetallic compounds to increase the strength of the steel.

**Table 3** Typical chemical compositions for some commercial stainless steel grades

<i>Steel grade</i>			<i>Microstructure</i>	<i>Typical chemical composition (wt%)</i>

S32205	S32205	1.4462	Duplex	22	5.5	3	0.17	
S32750	S32750	1.4410	Duplex	24	6	3	0.27	

**3.04.3.2.5 Manganese (Mn)**

Manganese is generally used in stainless steels to improve hot ductility. Its effect on the ferrite/austenite balance varies with temperature; at low temperatures, manganese is an austenite stabilizer, whereas at high temperatures, it will stabilize ferrite. Manganese increases the solubility of nitrogen and is used to obtain high nitrogen contents in austenitic steels.

**3.04.3.2.6 Silicon (Si)**

Silicon increases the resistance to oxidation, both at high temperatures and in strongly oxidizing solutions at lower temperatures. It promotes a ferritic structure.

**3.04.3.2.7 Carbon (C)**

Carbon is a strong austenite former and strongly promotes an austenitic structure. It also substantially increases the mechanical strength. Increasing carbon content reduces the resistance to intergranular corrosion. In ferritic stainless steels carbon will strongly reduce both toughness and corrosion resistance.

In the martensitic and martensitic–austenitic steels, carbon increases hardness and strength. In the martensitic steels, an increase in hardness and strength is generally accompanied by a decrease in toughness and in this way carbon reduces the toughness of these steels.

**3.04.3.2.8 Nitrogen (N)**

Nitrogen is a very strong austenite former and promotes an austenitic structure. It also substantially increases the mechanical strength of steel and enhances its resistance to localized corrosion, especially when used in combination with molybdenum. In ferritic stainless steels, nitrogen will lead to a significant reduction in toughness and corrosion resistance. In martensitic and martensitic–austenitic steels, the addition of nitrogen will increase hardness and strength but reduce the toughness of the steel.

**3.04.3.2.9 Titanium (Ti)**

Titanium is a strong ferrite former and a strong carbide former, and, as such, helps lower the effective

carbon content and promote a ferritic structure in two ways. In austenitic steels, it is added to improve the resistance to intergranular corrosion, but it also enhances the mechanical properties of the steel at high temperatures. In ferritic stainless steels, titanium is added to improve toughness and corrosion resistance by lowering the amount of interstitials in solid solution. In martensitic steels, titanium reduces the martensite hardness and increases the tempering resistance. In precipitation-hardening steels titanium is used to form the intermetallic compounds used to increase the strength of the steel.

#### 3.04.3.2.10 Niobium (Nb)

Niobium is both a strong ferrite and carbide former. Like titanium, it promotes a ferritic structure. In austenitic steels, it is added to improve the resistance to intergranular corrosion, but it also enhances mechanical properties at high temperatures. In martensitic steels, niobium reduces the hardness and increases the tempering resistance. It is also referred to as columbium (Cb).

#### 3.04.3.2.11 Aluminum (Al)

Aluminum improves the oxidation resistance, if added in substantial amounts. It is used in certain heat resistant alloys for this purpose. In precipitation-hardening steels, aluminum is used to form the intermetallic compounds that increase the strength in the aged condition.

#### 3.04.3.2.12 Cobalt (Co)

Cobalt is only used as an alloying element in martensitic steels in which it increases the hardness and tempering resistance, especially at higher temperatures.

#### 3.04.3.2.13 Vanadium (V)

Vanadium increases the hardness of martensitic steels due to its effect on the type of carbide present. It also increases tempering resistance. Vanadium stabilizes ferrite and will, at high contents, promote ferrite in the structure. It is only used in hardenable stainless steels.

#### 3.04.3.2.14 Sulfur (S)

Sulfur is added to certain stainless steels in order to increase the machinability. At the levels present in these grades, sulfur will substantially reduce corrosion resistance, ductility, and fabrication properties, such as weldability and formability.

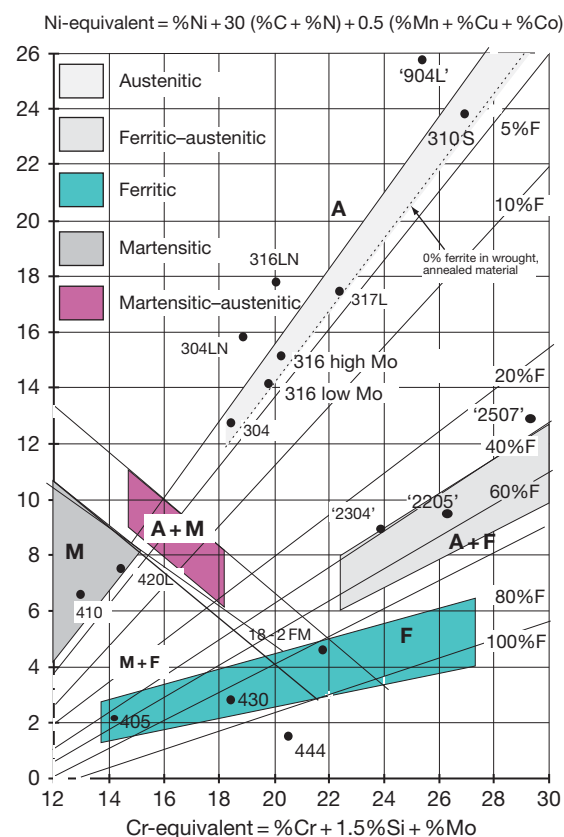

#### 3.04.3.2.15 Cerium (Ce)

Cerium is one of the rare earth metals (REMs) and is added in small amounts to certain heat-resistant,

high temperature steels and alloys in order to increase the resistance to oxidation and high temperature corrosion.

Since it is the combined effect of the alloying elements that decide both the microstructure and the properties of a certain grade, the effect of the alloying elements can be summarized in various ways. One such summary of the effect of alloying elements on the microstructure is the Schaeffler–Delong diagram presented in [Figure 4](#). A guide to the composition of the stainless steels presented in [Figure 4](#) is given in [Table 4](#).

The diagram is based on the fact that the alloying elements can be divided into ferrite-stabilizers and austenite-stabilizers. This means that they favor the formation of either ferrite or austenite in the microstructure of the steel. Assuming that the ability of austenite-stabilizers to promote the formation of austenite is related to the nickel content, and that the ability of ferrite-stabilizers is related to the chromium content, it becomes possible to calculate the total ferrite and austenite stabilizing effect of the alloying elements in the steel, and thereby obtain the

**Figure 4** The Schaeffler–Delong diagram. A guideline to the steel grades is presented in [Table 4](#).

chromium and nickel equivalents in the Schaeffler–Delong diagram. It is thus possible to take into account the combined effect of alloying elements on the microstructure of a steel grade.

The Schaeffler–Delong diagram was originally developed for weld metal, that is, it describes the structure after melting and rapid cooling, but the diagram has also been found to give a useful picture of the effect of the alloying elements for wrought and heat-treated material. However, in practice, wrought or heat-treated steels with ferrite contents in the range 0–5% according to the diagram in fact contain smaller amounts of ferrite than that predicted by the diagram. It should be noted that the Schaeffler–Delong diagram is not the only diagram for assessing the ferrite content and microstructure of stainless steels. Several other diagrams have been published, all with slightly different equivalents, phase limits, or general layout.

Precipitation-hardening stainless steels can be divided into three subcategories: martensitic, semiaustenitic, and austenitic grades. The common denominator here is not the microstructure but the hardening mechanism, precipitation hardening. This involves the formation of second-phase particles from a supersaturated solution which induces an internal strain in the microstructure and thus increases the strength of the material. The elements most commonly used to induce precipitation hardening, either individually or in combination, are aluminum, titanium, and copper.

### 3.04.4 Mechanical Properties

The difference in the mechanical properties of different stainless steels is perhaps seen most clearly in the stress–strain curves in **Figure 5**. The high yield and tensile strengths but low ductility of the martensitic steels are apparent, as are the low yield strength and excellent ductility of the austenitic grades. Duplex and ferritic steels both lie somewhere between these two extremes. Ferritic steels generally have a slightly higher yield strength than austenitic steels, whereas duplex steels have an appreciably higher yield strength than both austenitic and ferritic steels. The ductility of ferritic and duplex steels is of the same order of magnitude, even if the latter are somewhat superior in this respect.

#### 3.04.4.1 Mechanical Properties at Room Temperature

In terms of their mechanical properties, stainless steels can be roughly divided into four groups: martensitic, ferritic, duplex, and austenitic, and the properties within each group are relatively similar. **Table 5** shows the typical mechanical properties at room temperature for a number of stainless steels.

Stress values are given as the nearest 10 MPa. Standard deviations are normally about 20 MPa for proof strengths,  $R_{p0.2}$ ,  $R_{p1.0}$  and tensile strength,  $R_m$ ; and 3 wt% for the elongation,  $A_5$ . More detailed information can be found in Nordberg *et al.*<sup>4</sup>

Martensitic steels are characterized by their high strength and the fact that this strength is strongly affected by heat treatment. Martensitic steels are usually used in the hardened and tempered condition.

**Figure 5** Stress-strain curves for some stainless steels. Reproduced from Leffler, B. *Stainless – Stainless Steels and Their Properties*; Avesta Sheffield AB Research Foundation, Stockholm, Sweden, 1996.

In this condition, the strength of the steel improves in relation to the carbon content. Steels with more than 13 wt% chromium and a carbon content above 0.15 wt% are completely martensitic after hardening. A reduction in the carbon content causes an increase in the ferrite content and thus has an adverse effect on the strength of the steel. The ductility of martensitic steels is relatively low. Low carbon martensitic grades, often alloyed with nickel, have high strength in the hardened and tempered condition and good ductility. The mechanical properties of martensitic stainless steels are heavily influenced by the heat treatments to which the steels are subjected. A brief description of the general heat treatment of martensitic stainless steels and the effect on the mechanical properties is given as follows.<sup>5,6</sup>

To obtain useful properties, martensitic stainless steels are normally used in the hardened and tempered condition. The hardening treatment consists of heating to a high temperature in order to produce an austenitic structure with carbon in solid solution followed by quenching. The austenitizing temperature is generally in the range 925–1070°C. The effect of

**Table 5** Typical mechanical properties for stainless steels at room temperature for hot rolled plate

	1.4854	S35315	360	400	720	50

austenitizing temperature and time on hardness and strength varies with the composition of the steel, especially the carbon content. In general, the hardness will increase in relation to the austenitizing temperature up to a maximum and then decrease. The effect of increased time at the austenitizing temperature is normally a slow reduction in hardness with increased time. Quenching, after austenitizing, is done in air, oil, or water depending on the steel grade. On cooling below the  $M_s$  temperature, the starting temperature for the martensite transformation, the austenite transforms to martensite. The  $M_s$  temperature lies in the range 70–300°C and the transformation is usually completed at about 150–(200–248)°C below the  $M_s$  temperature. Almost all alloying elements will lower the  $M_s$  temperature, with carbon having the greatest effect. This means that in higher alloyed martensitic grades, the microstructure will contain retained austenite due to the low temperature (below ambient) needed to finish the transformation of the austenite into martensite.

In the hardened condition, the strength and hardness are high but the ductility and toughness is low. To obtain useful engineering properties, martensitic stainless steels are normally tempered. The tempering temperature used has a large influence on the final properties of the steel. The effect of tempering temperature on the mechanical properties of a martensitic stainless steel (Type 431) is shown in Figure 6. Normally, increasing tempering temperatures above 400°C will lead to a small decrease in tensile strength and an increase in reduction of area while hardness,

elongation, and yield strength are more or less unaffected. Above this temperature, there will be a more or less pronounced increase in yield strength, tensile strength, and hardness because of the secondary hardening peak, around 450–500°C. In the temperature range around the secondary hardening peak, there is generally a dip in the impact toughness curve. Above about 500°C, there is a rapid reduction in strength and hardness, and a corresponding increase in ductility and toughness. Tempering at temperatures above the AC1 temperature (780°C for the steel in Figure 6) will result in partial austenitizing and the possible presence of nontempered martensite after cooling to room temperature.<sup>7</sup>

Ferritic steels have relatively low yield strength and the work hardening is limited. The strength increases as the carbon content is increased, but the effect of increased chromium content is negligible. However, ductility decreases at high chromium levels and good ductility requires very low levels of carbon and nitrogen.

Duplex (ferritic–austenitic) steels have a high yield strength, which increases with higher carbon and nitrogen levels. Increased ferrite content will, within limits, also increase the strength of duplex steels. Their ductility is good and they exhibit strong work hardening properties.

Austenitic steels generally have a relatively low yield strength and are characterized by strong work hardening properties. The strength of austenitic steels increases with higher levels of carbon, nitrogen, and, to a certain extent, also molybdenum. The detrimental effect of carbon on corrosion resistance

**Figure 6** Effect of tempering temperature on the mechanical properties ( $R_{p0.2}$  – 0.2% proof strength).

means that this element cannot be used for increasing strength. Austenitic steels exhibit very high ductility; they have a high elongation and are very tough.

Some austenitic stainless steels with a low overall content of alloying elements, for example, type 301 and 304 steels, can be metastable and may form martensite, either due to cooling below ambient temperatures or through cold deformation, or a combination of both. The formation of martensite will cause a considerable increase in strength, as illustrated in **Figure 7**. The  $M_d$  temperature is defined as the temperature below which martensite will form. The stability of the austenite depends on the composition of the steel; the higher the content of alloying elements, the more stable the austenite. A common equation for relating austenite stability to alloy composition is the  $M_{d30}$ , which is defined as the temperature at which martensite will form at a strain of 30%:

$$M_{d30} = 551 - 462(C + N) - 9.2Si - 8.1Mn - 13.7Cr - 29(Ni + Cu) - 18.5Mo - 68Nb - 1.42(GS - 8.0)(^{\circ}C)$$

where GS is the grain size, ASTM grain size number.

This type of equation gives a good idea of the behavior of lean austenitic stainless steels, but it must be noted that it is only approximate as interactions between the alloying elements are not taken into account.

The effects of alloying elements and structure on the strength of austenitic and duplex steels have been discussed over the years and several regression equations have been proposed for identifying the effects of the various alloying elements in stainless steels. Most of the regression equations proposed apply to austenitic stainless steels but some have also included duplex stainless steels in the equations.<sup>8,9,10</sup> These

**Figure 7** The effect of strain on martensite and yield strength of AISI 301. Reproduced from Peckner, B. *Handbook of Stainless Steel*; McGraw-Hill, 1977.

equations may be used to estimate the strength of austenitic and duplex steel.

In contrast to the constructional steels, austenitic steels do not exhibit a clear yield stress but begin to deform plastically at a stress around 40% of the tensile strength,  $R_{p0.2}$ .

It should be noted that although the different elements are included in the equation through rather simple expressions, the actual strengthening mechanism might be more complex. At chromium contents over 20%, austenitic steel with 10% Ni will contain  $\delta$ -ferrite, which in turn causes a smaller grain size, and this will enhance both yield strength and tensile strength. Nitrogen has a strong strengthening effect but is also a powerful austenite stabilizer. In duplex stainless steels, the strengthening effect of nitrogen is, to a certain extent, countered by the increased austenite content caused by the addition of nitrogen.

#### 3.04.4.2 The Effect of Cold Work

Stainless steels will harden during deformation and the mechanical properties of stainless steels are strongly influenced by cold deformation. The amount of hardening depends on both the composition and the type of steel. The work hardening of austenitic and duplex steels in particular causes considerable changes in properties after cold forming operations. The general effect of cold work is to increase the yield and tensile strengths and at the same time decrease the elongation. **Figure 8** shows cold hardening curves for some stainless steels.

The work hardening is greater for austenitic steels than for ferritic steels. The addition of nitrogen in austenitic steels makes these grades particularly hard and strong: compare S31603 and S31653. The strong work hardening of the austenitic steels means that large forces are required for forming operations even though the yield strength is low. Work hardening can, however, also be deliberately used to increase the strength of a component.

#### 3.04.4.3 Toughness

The toughness of the different types of stainless steel shows considerable variation, ranging from excellent toughness at all temperatures for austenitic steels to the relative brittleness of martensitic steels.

Toughness is dependent on temperature and generally increases with increasing temperature. One measure of toughness is impact toughness, that

is, the toughness measured on rapid loading. **Figure 9** shows the impact toughness for different categories of stainless steel at temperatures ranging from  $-200$  to  $+100^{\circ}\text{C}$ . It is apparent from the diagram that there is a fundamental difference at low temperatures between austenitic steels on the one hand and martensitic, ferritic, and duplex steels on the other.

The martensitic, ferritic, and duplex steels are characterized by a transition in toughness, from tough to brittle behavior, at a certain temperature, the transition temperature. For the ferritic steel, the transition temperature increases with increasing carbon and nitrogen content, that is, the steel becomes brittle at successively higher temperatures. For the duplex steels, increased ferrite content gives a higher transition temperature,

**Figure 8** Effect of cold work on some stainless steels. Reproduced from Leffler, B. *Stainless Steels and Their Properties*, 2nd revised ed.; Outokumpu Stainless Research Foundation, Stockholm, 1998.

**Figure 9** Impact toughness for different types of stainless steels.

that is, more brittle behavior. Martensitic stainless steels have transition temperatures around or slightly below room temperature, while those for the ferritic and duplex steels are in the range  $0$ – $60^{\circ}\text{C}$ , with the ferritic steels in the upper part of this range.

The austenitic steels do not exhibit a toughness transition as the other steel types but have excellent toughness at all temperatures. Austenitic steels are thus preferable for low-temperature applications.

### 3.04.4.4 Fatigue Properties

During cyclic loading, stainless steels, like other materials, will fail at stress levels considerably lower than the tensile strength measured during tensile testing. The number of load cycles the material can withstand is dependent on the stress amplitude. **Figure 10** shows how the lifetime, that is, the number of cycles to failure, increases with decreasing load amplitude until a certain amplitude is reached, below which no failure occurs. This stress level is called the fatigue limit. In many cases, there is no fatigue limit, but the stress amplitude shows a slow decrease with an increasing number of cycles. In these cases, the fatigue strength, that is, the maximum stress amplitude for a certain time to failure (number of cycles) is called the fatigue strength and it is always given in relation to a certain number of cycles.

The fatigue properties of ferritic–austenitic and austenitic stainless steels with a fatigue limit at a lifetime of  $10^6$ – $10^7$  load cycles can be described by the Wohler curve or  $S$ – $N$  curve and related to their tensile strength, as shown in **Table 6**. The relation between the fatigue limit and tensile strength is also

**Figure 10**  $S$ – $N$  curve (Wohler curve) for an austenitic stainless steel of Type S31600 (hMo) in air.  $S$  – stress amplitude,  $N$  – number of cycles. Reproduced from Leffler, B. *Stainless Steels and Their Properties*, 2nd revised ed.; Outokumpu Stainless Research Foundation, Stockholm, 1998.

**Table 6** Fatigue properties of stainless steels, relation between tensile strength and fatigue strength

Microstructure	$S_o/R_m$ , Stress ratio		Maximum stress
	$R=-1$	$R=0$	
Ferritic	0.7	0.47	Yield strength
Austenitic	0.45	0.3	Yield strength
Duplex	0.55	0.35	Yield strength

dependent on the type of load, which is the stress ratio ( $R$ ). The stress ratio is the ratio of the minimum stress to the maximum stress during the loading cycle. The compressive stresses are defined as negative.

### 3.04.5 Precipitation and Embrittlement

Under various circumstances, the different stainless steel types can suffer undesirable precipitation reactions, which can cause a decrease in both corrosion resistance and toughness.

#### 3.04.5.1 Embrittlement at 475°C

If martensitic, ferritic, or duplex steels are exposed to temperatures in the range 350–550°C, a serious decrease in toughness will occur after some time. The phenomenon is encountered in grades containing more than 15–18% chromium and the origin of this embrittlement is the decomposition of the ferrite into two phases of body-centered cubic, bcc, structure,  $\alpha$  and  $\alpha'$ . The former is very rich in iron and the latter very rich in chromium. This type of embrittlement is usually called 475°C embrittlement after the midpoint of the temperature range.

#### 3.04.5.2 Carbide and Nitride Precipitation

If ferritic steels are heated to temperatures above approximately 950°C, they suffer precipitation of chromium carbides and chromium nitrides during the subsequent cooling, which cause a decrease in both toughness and corrosion resistance. This type of precipitation can be reduced or eliminated by decreasing the levels of carbon and nitrogen to very low levels and/or stabilizing the steel by additions of titanium as in 18Cr–2Mo–Ti.

Carbide and nitride precipitation in austenitic and duplex steels occurs in the temperature range 550–800°C. Chromium-rich precipitates form in the grain boundaries and can cause intergranular

corrosion and, in extreme cases, even a decrease in toughness. However, during the short times in the critical temperature range experienced in the heat-affected zone adjacent to welds, the risk of deleterious precipitation is very small for the low-carbon steels.

#### 3.04.5.3 Intermetallic Phases

In the temperature range 700–900°C, iron alloys with a chromium content above about 17% form intermetallic phases such as  $\sigma$  phase,  $\chi$  phase, and Laves phase. These phases all have high chromium content and are brittle and consequently large amounts of these phases in the microstructure will lead to a drop in toughness and a decrease in resistance to certain types of corrosion.

Chromium, molybdenum, and silicon promote the formation of intermetallic phases, so the majority of ferritic, duplex, and austenitic steels show some propensity to form these phases. Intermetallic phases form most readily from highly alloyed ferrite. In ferritic and duplex steels, intermetallic phases therefore form readily but are, on the other hand, relatively easy to dissolve on annealing. In the austenitic steels, it is the highly alloyed grades that are particularly susceptible to intermetallic phase formation. The low chromium content and low molybdenum grades are considerably less sensitive to the precipitation of these phases.

Heat treatment may remove all types of precipitates by redissolving them. Renewed heat treatment of martensitic steels and solution annealing and quenching ferritic, duplex, or austenitic steels restore the microstructure. Relatively long times or high temperatures may be required for the dissolution of intermetallic phases in highly alloyed grades.

Stainless steels can pick up nitrogen if exposed to nitrogen-containing atmospheres such as nitrogen, nitrogen mixtures, and cracked ammonia. During nitrogen pick-up, nitrides and other brittle compounds of chromium, molybdenum, titanium, vanadium, and aluminum can form. Atmospheric oxygen, even at relatively low levels, reduces the risk for nitridation. At temperatures between 400 and 600°C, a layer of nitrides is formed at the steel surface; at higher temperatures, nitrogen uptake and nitride formation occur throughout the material. Nitridation, that is, nitride formation, causes chromium depletion and reduced oxidation resistance in the same way as carburization. This can lead to catastrophically high oxidation rates on the outer surface of equipment, which is subjected to a nitriding atmosphere on the inside – for example, the muffles in annealing

furnaces. Nitrogen pick-up can also cause embrittlement because of to surface or internal nitride formation. Nickel is the alloying element, which provides the greatest protection against nitridation, as nickel does not form stable nitrides.

#### 3.04.5.4 Carburization

If a material is exposed to gases containing carbon, for example, in the form of CO, CO<sub>2</sub>, or CH<sub>4</sub>, it can pick up carbon. The degree of carburization is governed by the levels of carbon and oxygen in the gas, also the temperature and steel composition. The carbon, which is picked up by the steel will largely form carbides, primarily chromium carbides.

The formation of a large amount of chromium carbides causes chromium depletion and thus a reduced resistance to oxidization, because carbides, or even a network of carbides, form in the grain boundaries as well as within the grains. The resistance to thermal cycling is reduced and, since carburization leads to an increase in volume, there is a danger of cracks developing in the material. Carbon pick-up can occur even at relatively low temperatures (400–800°C) in purely reducing–carburizing atmospheres and gives rise to catastrophic carburization or metal dusting. Attack is severe and characterized by ‘powdering’ of the steel surface because of the breakdown of the protective oxide layer and inward diffusion of carbon, which forms grain boundary carbides. The increase in volume on carbide formation means that grains are rapidly broken away from the steel surface, giving rapid and serious attack.

Chromium, nickel, and silicon are the alloying elements, which most improve resistance to carburization.

#### 3.04.5.5 Heat Treatment

The aim of heat treatment of stainless steels is to restore the microstructure after forming or other fabrication and production operations thereby removing or at least minimizing any possible negative effects. However, in the case of the hardenable stainless steels, that is, martensitic and precipitation-hardening grades, heat treatment is used to set the mechanical properties at the required level. In other cases, that is, stress relief heat treatment, the aim is to reduce the level of residual stresses caused by fabrication operations such as cold forming and welding.

##### 3.04.5.5.1 Solution annealing

Solution annealing is the most common heat treatment for ferritic, austenitic, and duplex stainless

steels, that is, the types of stainless steel in which the mechanical properties cannot be set by heat treatment. Instead the aim of the heat treatment is to restore the microstructure by allowing recrystallization to occur and deleterious phases, such as carbides and intermetallic phases, to be dissolved.

During solution annealing the material is heated to a temperature where detrimental phases will be dissolved, held at temperature for a time long enough to allow the unwanted phases to dissolve, and then rapidly cooled or quenched. Solution annealing is normally performed on austenitic and duplex stainless steels at temperatures above 1020°C. A higher alloying content will normally require a higher solution annealing temperature in order to produce a precipitate-free microstructure. For the stabilized austenitic grades, the temperature used should allow chromium carbides and other unwanted phases to dissolve but should be low enough to retain the titanium or niobium carbides used to stabilize the steel. Ferritic stainless steels are normally only annealed using temperatures below 1000°C. **Table 7** presents typical heat treatment as solution annealing or annealing temperatures for stainless steels.

Rapid cooling after heat treatment is normally required to ensure that unwanted reactions in the microstructure do not occur. Whether air- or water-cooling is required depends on parameters such as section thickness and the type of steel. It is not the cooling rate *per se* that is important, but the time spent in the temperature range in which precipitation or other unwanted reactions may occur. Higher alloyed grades and thicker sections will thus generally require water quenching rather than air-cooling.

##### 3.04.5.5.2 Quenching, tempering, and ageing

##### Martensitic grades

Heat treatment of the martensitic stainless steels is essentially the same as the heat treatment of other hardenable steels. The difference is that the high

**Table 7** Heat treatment temperatures for ferritic, austenitic and duplex stainless steels

Category	Temperature (°C)	Quenching
Ferritic	700–850	Water/forced air
Ferritic (high alloyed)	750–950	Water/forced air
Austenitic	1020–1100	Water/forced air
Austenitic (high alloyed)	1080–1200	Water
Duplex	1020–1150	Water

alloy content slows the transformation reactions and increases hardenability.

The normal heat treatment cycle of martensitic stainless steels is

1. hardening by austenitizing at temperatures of 950–1050°C followed by quenching in oil or water, and
2. tempering at temperatures of 300–700°C to set final properties.

Quenched hardness will increase with increasing austenitizing temperature in the lower end of the temperature range, but austenitizing in the high end of the temperature range will lower the as-hardened hardness.

Tempering is designed to allow the material to reach an optimum between strength and ductility. The tempering temperature is thus dependent on the strength level specified and these may normally be found in the appropriate product standards.

#### **Precipitation hardening Grades**

These steels can be divided into three subcategories: martensitic, semiaustenitic, and austenitic grades. All of the precipitations hardening grades depend on a precipitation reaction to induce the strengthening during aging. The precipitates may differ from grade to grade, but the principle is that a solution anneal is used to put some alloying elements into solution at high temperature followed by quenching to low temperature at which a supersaturated solution is obtained. Ageing at an elevated temperature will then cause the precipitation and hardening resulting in an increased strength. The heat treatment cycles of the different types of precipitation-hardening steels can be summarized as follows:

1. Martensitic grades
  - a. solution anneal in the austenite region (1020–1050°C)
  - b. quench to room temperature
  - c. age at 470–630°C to produce precipitation and hardening
2. Semiaustenitic grades
  - a. solution anneal in the austenite region (1020–1050°C)
  - b. quench to room temperature followed by sub-zero cooling or tempering at about 750°C
  - c. age at 470–570°C to produce precipitation and hardening
3. Austenitic grades
  - a. solution anneal (1000–1100°C)
  - b. quench to room temperature
  - c. age at 700–800°C to produce precipitation and hardening

#### **3.04.5.5.3 Stabilization annealing**

A stabilization heat treatment is applied to titanium- or niobium-stabilized grades in order to enhance the resistance to intergranular corrosion, that is, to make sensitization more difficult. The aim of this treatment is to ensure that the carbon dissolved in the matrix is forced to combine with the stabilizing element, for example, titanium or niobium, thus becoming securely locked up in as titanium or niobium carbides and therefore not unavailable for chromium carbide formation.

Titanium and niobium both form more stable carbides than do chromium and these carbides precipitate at higher temperatures than do chromium carbides. The stabilizing treatment therefore consists of heat treatment at a temperature slightly above the temperature range for chromium carbide precipitation. The temperature selected is normally in the range as low as possible in order to obtain maximum driving force for the precipitation. Stabilization heat treatment is usually performed at temperatures in the range 850–980°C on material that has previously been solution annealed. The lower part of the temperature range should be used with some caution, as this type of treatment is not equally effective in all environments.

### **3.04.6 Physical Properties**

The physical properties of the different stainless steels are dependent on both the microstructure (crystal structure) and the amount of alloying elements added. In many cases the physical properties cannot be manipulated by heat treatment or fabrication practices and are more or less 'locked' in the atomic arrangement of the steel. Again, the grouping of the property values follows the division of steel grades into the main stainless categories.

Ferromagnetism is a characteristic property of ferrite and martensite while austenite is not ferromagnetic. This means the ferritic and martensitic stainless steels are strongly magnetic while the fully austenitic stainless steels are nonmagnetic. However, since many of the more common and lower alloyed austenitic grades contain small amounts of ferrite they might show a weak magnetic behavior. The duplex steels containing about 40–60% ferrite will naturally be magnetic even if their magnetism is weaker than that of the ferritic or martensitic stainless steels.

Regarding the other physical properties it may be noted that the thermal expansion is strongly related to

the microstructure and this gives the austenitic steels a thermal expansion that is about 50% higher than that of the ferritic and martensitic stainless steels. The thermal conductivity is lower for austenitic steels compared with that of the ferritic or martensitic steels and within each category the thermal conductivity decreases with increasing alloying content. Other properties such as thermal capacity and the modulus of elasticity show relatively little variation across the different stainless steel categories. The most highly alloyed austenitic grades have a somewhat lower modulus compared with other stainless steels.

Typical values of the physical properties for the some stainless steels from the different categories are shown in [Table 8](#).<sup>11,12</sup>

### 3.04.7 Property Relationships for Stainless Steels

Martensitic and martensitic–austenitic stainless steels are characterized by their high strength but limited corrosion resistance. An increased carbon content increases strength, but at the expense of lower toughness and considerable degradation of weldability. The martensitic 13% chromium steels, with higher carbon contents, are not designed to be welded, even though it is possible under special circumstances. In order to increase high temperature strength, alloying with strong carbide formers such as vanadium and tungsten are used. An increase in

the nickel content also increases toughness. In contrast to the martensitic steels, the martensitic–austenitic steels do not have to be welded at elevated temperatures except in thick sections; even then only limited preheating is required.

The areas of use of martensitic and martensitic–austenitic steels are naturally those in which the high strength is an advantage and the corrosion requirements are relatively low. The martensitic steels with low carbon contents and the martensitic–austenitic steels are often used as stainless constructional materials. The martensitic steels with high carbon content are used for springs, surgical instruments, and for sharp-edged tools such as knives and scissors.

The ferritic steels are characterized by good corrosion properties, very good resistance to chloride-induced stress corrosion cracking (SCC), and moderate toughness. The toughness of ferritic stainless steels is generally not particularly high. Lower carbon and nitrogen levels give a considerable improvement in both toughness and weldability, although toughness is limited for thicker dimensions. Consequently ferritic steels are usually only produced and used in thinner dimensions. Ferritic stainless steels are used in household products and in applications with fairly low demands of the corrosion resistance of the material in combination with aesthetic reasons. Examples of such application areas are cookware lids, washing machine drums, refrigerator doors etc. They have stress–strain data similar to carbon steel; generally have higher yield strength than the austenitic stainless steels. Their

RT, room temperature.

thermal conductivity is high and they transmit heat efficiently, which is one of the reasons to frequent use in electric irons and heat exchangers. They have further a low thermal expansion coefficient, lower than for the austenitic stainless steels, which give them less distortion when heated. Ferritic stainless steels are widely used in large tonnage all over the world.

The modern duplex steels span the same wide range of corrosion resistance as the austenitic steels depending on the alloy composition. Duplex equivalents can be found to both the ordinary austenitic grades, such as S31600 (1.4401), and to the high-alloyed austenitic grades, such as S31254 (1.4547). The corrosion resistance of S32304 (1.4362) type duplex is similar to that of S31600 (1.4401) while S32205 (1.4462) is similar to N08904L (1.4539) and S32750 (1.4410) is similar to the high-alloyed austenitic grades with 6% molybdenum, such as S31254 (1.4547). High strength, good toughness, and very good corrosion resistance characterize the duplex steels in general and excellent resistance to chloride-induced SCC and corrosion fatigue in particular. An increased level of chromium, molybdenum, and nitrogen increases corrosion resistance, while the higher nitrogen level also contributes to a further increase in strength above that associated with the duplex structure. Applications of duplex steels are typically those requiring high strength, good corrosion resistance and low susceptibility to SCC or combinations of these properties. The lower alloyed S32304 (1.4362) is used for applications requiring corrosion resistance similar to S31600 (1.4401) or lower and where strength is an advantage. Some examples of such applications are: hot water tanks in the breweries, pulp storage towers in the pulp and paper industry, tanks for storage of chemicals in the chemical process industry, and tank farms in tank terminals in the transportation industry. The higher alloyed S32205 (1.4462) is, for example, used in pulp digesters and storage towers in the pulp and paper industry where it is rapidly becoming a standard grade. It is also used in piping systems, heat exchangers, tanks and vessels for chloride-containing media in the chemical industry, in piping and process equipment for the oil and gas industry, in cargo tanks in ships for transport of chemicals, and in shafts, fans, and other equipment which require resistance to corrosion fatigue. High alloyed grades, for example, S32750 (1.4410), are used in piping and process equipment for the offshore industry, that is, oil and gas and in equipment for environments containing high chloride concentrations, such as seawater.

Very good corrosion resistance, very good toughness, and very good weldability characterize the austenitic steels. They are also the most utilized stainless steels. Resistance to general corrosion, pitting, and crevice corrosion generally increases with increasing levels of chromium and molybdenum. The low-carbon grades exhibit good resistance to intergranular corrosion and consequently the higher alloyed steels are only available with low carbon contents. Austenitic steels are generally susceptible to chloride-induced SCC; only the highly alloyed steels such as N08904 (1.4529), and S31254 (1.4547) exhibit good resistance to this type of corrosion.

The austenitic stainless steels are used in almost all types of applications and industries. Typical areas of use include piping systems, heat exchangers, tanks and process vessels for the food, chemical, pharmaceutical, pulp and paper, and other process industries. Nonmolybdenum alloyed grades, for example, S30400, are normally not used in chloride-containing media but are often used where demands are placed on cleanliness or in applications in which equipment must not contaminate the product. The molybdenum-alloyed steels are used in chloride-containing environment with the higher alloyed steels, N08904, S31254, being chosen for higher chloride contents and temperatures. S31254 is used to handle seawater at moderate or elevated temperatures. Applications include heat exchangers, piping, tanks, process vessels, etc. within the offshore, power, chemical and pulp- and paper industries. The low-alloyed grades, especially S30400 and S31600, are used in equipment for cryogenic applications. Examples are tanks, heaters, evaporator, and other equipment for the handling of condensed gases such as liquid nitrogen. Finally it is worth mentioning that austenitic stainless steels are often used in applications requiring non-magnetic materials since they are the only nonmagnetic steels.

### 3.04.8 Corrosion Properties of Stainless Steels

Stainless steels are widely used throughout the world in a variety of applications in both industrial and domestic environments, for example, as a construction material, in the manufacture of everyday utensils. The use of stainless steels has been growing steadily and new areas of application, often in demanding service environments, are constantly being developed. The serviceability of stainless steels

in many of these applications is determined by the material properties of the steels and how they perform when exposed to different service environments. Historically, the success stories of stainless steel usage have been widely accounted for in corrosion engineering. Extensive research has been carried out with the aim of reducing further the risk of various types of corrosion by choosing appropriate stainless steel grades for specific service environments. The following chapter is intended as a guide for explaining the different types of corrosion mechanisms that can affect stainless steel and their causes. This section also aims to increase the knowledge of stainless steels and their corrosion resistance in different service environments. Depending on the service environment involved, several types of corrosion may affect stainless steels.

**Figure 11** shows part of a stainless steel pipe after service in a very severe corrosive environment consisting of high amounts of chlorides, water, and oxygen in combination with high temperatures under evaporative conditions. The pipe suffered from several corrosion forms that affect stainless steels, notably pitting corrosion, crevice corrosion and SCC.

#### 3.04.8.1 Passivity

The reason for the good corrosion resistance of stainless steels is that they form a very thin, invisible

**Figure 11** SCC, crevice corrosion, and pitting corrosion on a stainless steel pipe, after service in a very aggressive environment consisting of high amounts of chlorides, water, and oxygen in combination with high temperatures under evaporative conditions. Photo: Outokumpu Stainless.

surface film, so called passive film or passive layer in oxygen containing environments. The passive film is mainly a chromium oxide, which protects the steel from corrosion attack in an aggressive environment. For a passive film to form on a stainless steel surface, a certain amount of chromium is required in the steel as an alloying element. As chromium is added to steel, a rapid reduction in corrosion rate is observed around 10 wt% because of the formation of this protective layer or passive film, as illustrated in **Figure 12**.

The commercial alloys of austenitic stainless steels typically contain between 16 and 28 wt% of chromium, while the chromium content of ferritic stainless steels ranges from 10.5 to 30 wt%. The chromium content varies in martensitic stainless steels, from 11.5 to 18 wt% and in duplex stainless steels; it is usually between 21 and 29 wt%. A passive film on a stainless steel surface consists of an inner layer of mixed iron/chromium oxides and an outer layer of chromium hydroxide. This film has self-healing properties when damaged in the presence of oxygen and a repair of the passive film can easily form after a scratch or other surface damage.

The thickness of a passive film is commonly considered to be in the range of 1–3 nm, depending on the service environment and the steel grade, but it also depends on pH values and the electrochemical properties in contact with a surrounding solution.

#### 3.04.8.2 Contribution of Main Alloy Elements to Passivation

As already indicated, chromium is the most important alloying element for corrosion resistance in stainless steels as it helps to form a passive film on

**Figure 12** The effect of chromium content on passivity. Reproduced from Design Guidelines for the selection and use of stainless steel, specialty steel industry of the United States, Washington, DC, USA.

the surface. The spontaneous formation of intact chromium oxide on the surface acts as a barrier layer and the surface electrochemistry is changed as a result of equilibrium reactions between the passive film and any surrounding solution.

It is also well-accepted and proved that the addition of molybdenum, as an alloying element, offers an efficient method for preventing corrosion in stainless steel by improving the passive film properties. The molybdenum content in stainless steels can be as much as 8%. However, the exact mechanism of detailed chemistry of molybdenum in a passive film with respect to passivity, interaction, and formation of compounds is the subject of extensive discussion, since molybdenum as an alloying element shows a complex oxide chemistry in the passive film with many oxidation stages.

The addition of nitrogen contributes to enhancing the resistance to pitting and crevice corrosion on austenitic stainless steels.<sup>14</sup> As the nitrogen stays soluble in the stainless steel, without any precipitation, the localized corrosion resistance is improved for rather high amounts. However, if nitrides are formed in the stainless steel the corrosion resistance is drastically decreased. More about nitride precipitation can be read in [Section 3.04.5](#).

Nickel contributes to improved corrosion properties by assisting the repassivation process and helping reduce the rate of corrosion, for example, in strong acid solutions.

### 3.04.8.3 General Electrochemical Considerations in Corrosion of Stainless Steels

The basic electrochemical reactions for corrosion are that the metal, Me, is defined as the anode and balances the oxygen reduction attributed to the cathode.

In the classical electrochemical oxygen cathodic reaction there are two pathways accepted for the reduction according to.

(neutral or alkaline environment)

The oxygen reduction is, however, a known complex process with many proposed pathway, for example:

Four electron pathway:

Two electron pathway:

The reduction pathway is influenced by many factors, for example, the surface composition of the electrodes.

In strongly reducing environments, reduction of hydrogen ions is often the cathodic reaction to balance the metal dissolution:

The oxidation of a metal, that is, corrosion, requires always a counter balance by a reduction.

A common test procedure for the investigation of stainless steel's resistance to corrosion in wet environments is to perform dynamic anodic polarization measurements in a conductive solution to obtain a polarization curve. [Figure 13](#) shows a schematic polarization curve undertaken for a stainless steel presenting the different potential area and the current density response.

The high current densities shown in [Figure 13](#) represent a corrosion process and the very low current response represents the passivity of a stainless steel. At low cathodic potentials, a line of high current densities represents the cathodic reaction. At the potential, when the cathodic reaction and the anodic reaction meet in the active area on occurring corrosion is denoted the corrosion potential,  $E_{\text{corr}}$ .

At the higher anodic potential, the passivity is represented by a decrease in current densities corresponding to the passivation current to stabilize in the passive potential area to a very low current density, the passive current density. Pitting corrosion or crevice corrosion is typically represented by a steep increase in the current response at an even higher potential, the pitting potential,  $E_p$ . Transpassive corrosion is represented by an increase in current density response in a rather extended potential area at even higher anodic potentials, associated with the transpassive potential,  $E_{\text{tr}}$ . In order to investigate the ability of a stainless steel to repassivate in, for example, chloride environment, a reverse scan is commonly performed while performing polarization measurements. The current response on the repassivation process is a clear decrease in the passive current and the potential for the steep decrease is noted repassivation potential,  $E_{\text{rp}}$ .

**Figure 13** Schematic polarization curve for a stainless steel.

#### 3.04.8.4 Breakdown of Passivity

All corrosion forms on stainless steels are related to any permanent damage of the passive film, either as a complete breakdown of the film causing uniform corrosion or locally as in pitting and crevice corrosion. Intergranular corrosion occurs along grain boundaries due to local breakdown of the passive film where chromium has been depleted. Once the passivity of stainless steel is broken down, completely or locally, and repassivation is not promoted by the aggressiveness of the surrounding solution, active corrosion occurs.

Local breakdown such as pitting and crevice corrosion is commonly initiated in neutral solutions, but can also occur in solutions with a low pH. The general aspect to consider in pitting and crevice corrosion is the very fast corrosion rate that can cause penetration through the steel in a short time and may lead to catastrophic failure.

Complete breakdown of the passive film causing uniform corrosion may occur in solutions of either low or high pH. Uniform corrosion or general corrosion occurs when the passive layer on a stainless steel surface breaks down partly or completely. The corrosion then propagates at a rate determined by a corrosive environment and the alloy composition in combination. Uniform corrosion causes a corrosion rate that can be expressed as a mean value of the attacked surface, making it possible to calculate a material loss, from weight loss determinations.

An even worse type of corrosion from the construction service point of view is SCC, which is characterized by the cracking of materials that are subjected to both a tensile stress and a corrosive environment. Most reported failures due to SCC occur in the standard stainless steel grades S30400 and S31600 with tensile stress in aqueous solutions containing chlorides at elevated temperatures,  $>60^{\circ}\text{C}$ . However, solutions containing chlorides are not the only environments that cause SCC in stainless steels. Similar cracking can also occur in hot caustic solutions and in environments containing impurities such as hydrogen sulfide.

#### 3.04.8.5 Localized Corrosion – Pitting and Crevice Corrosion

Smialowska recently reviewed the tremendous work performed on pitting and crevice corrosion and the use of electrochemistry to characterize stainless steel regarding pitting and crevice corrosion.<sup>15</sup> Detailed information about pitting and crevice corrosion and the historical research can be read in this review.

Defects in the passive film enhance the risk of pitting and crevice corrosion. Manganese sulfides are identified to be initiation points to pitting and crevice corrosion. However, in modern commercial stainless steels, the sulfur content is normally so low that there are only few recent reports about sulfur causing pitting corrosion.

Environments, which represent the greatest risk of pitting and crevice corrosion of stainless steels,

include seawater and process solutions in which there is a high concentration of chlorides sometimes also in combination with an increased temperature. High halide concentration, commonly chlorides, low pH, and high temperature increase the probability of pitting and crevice corrosion on stainless steels. Pitting corrosion may also be caused by the presence of thiosulphate in combination with chloride ions. The risk of pitting corrosion increases when the relative levels of thiosulfate, sulfate, and chloride reach a certain amount, but can be avoided by controlling the amount of thiosulfate.

Different types of formulas have been proposed to rank the resistance of stainless steels to pitting corrosion and to compare a steel grade among other grades by the influence of main alloying elements. The pitting resistance equivalent (PRE) of a specific steel grade can be estimated by formulas in which the relative influence of a few elements, that is, chromium, molybdenum, and nitrogen, are considered. The higher the PRE value of a stainless steel, the better the resistance to pitting corrosion in neutral chloride containing solutions. Table 9 shows the compositions of some commercial stainless steels and calculated PRE, indicating their relative pitting corrosion resistance.

One frequently used expression is:

$$\text{PRE} = \% \text{Cr} + 3.3\% \text{Mo} + 16\% \text{N}$$

There are also other formulas with different alloying elements included, such as manganese, wolfram, sulfur, and carbon.

Alfonsson and Qvarfort investigated some formulas for PRE, based on the chromium, molybdenum, and nitrogen content and compared the PRE values with critical pitting temperatures (CPT) measured potentiodynamically, using the Avesta cell.<sup>16</sup> They found an acceptable linearity between the CPT and PRE values for any of the PRE formulas studied.

### 3.04.8.5.1 Influence of alloy composition on localized corrosion

The increase in the chromium content and molybdenum content enhances the passive potential area to more anodic potentials and consequently increases the stainless steel's ability to passivate in more aggressive solutions. The higher alloyed stainless steel grades, for example, those containing 6% of molybdenum, do not often show any pitting potential due to pitting corrosion in polarization measurements at room temperature, and elevated temperatures are often required to break down the passivity in high amounts of chlorides.

Horvath and Uhlig investigated the influence of chromium, nickel, and molybdenum on the pitting potential in sodium chloride, NaCl, and sodium bromide, NaBr. They showed that the alloying elements, which had the greatest influence on the pitting

**Table 9** Typical chemical compositions and PRE numbers for some commercial stainless steel grades

S32750	1.4410	Duplex	24	6	3	0.27		38

potential, were chromium and molybdenum. The addition of nickel resulted in a minor increase of the pitting potential compared with the results obtained by the addition of chromium and molybdenum.<sup>17</sup> **Figure 14** shows the influence of alloying elements on pitting potentials in NaCl extracted from Horvath and Uhlig.<sup>17</sup> Comparing the data with an increasing addition of chromium in a Cr–Fe alloy, the pitting potential was around 0.2 V/SHE for 20 wt% chromium, which rose to around 0.9 V/SHE at 38 wt% of chromium. For nickel in a 15% Cr–Fe alloy, the pitting potential was at 20% Ni, 0.28 V/SHE, which at 40 wt% Ni increased to only 0.35 V/SHE. In contrast to the low increase in the pitting potential produced by the addition of nickel, the addition of molybdenum produced a significant influence, even at very low amounts. The pitting potential increased from 0.3 V/SHE for 0.48 wt% up to 0.76 for 2.4 wt% in a 15%Cr–13%Ni stainless steel.

As previously mentioned the presence of nitrogen increases the resistance of pitting and crevice corrosion on stainless steels. Jargelius-Pettersson showed that the effect of nitrogen was depressing both the active dissolution and passive current. The author also showed that the positive effect was pronounced in combination with molybdenum.<sup>18</sup> There are further methods to increase the surface content of nitrogen to enhance the pitting and crevice corrosion resistance of a stainless steel.

#### 3.04.8.5.2 Pitting corrosion

Pitting is a type of localized corrosion that is characterized by attacks at small discrete spots on the stainless steel surface. The pits often appear to be

**Figure 14** Dependence of chromium, nickel and molybdenum in 0.1 M NaCl at 25 °C. Reproduced from Horvath, J.; Uhlig, H. H. *J. Electrochem. Soc.* **1968**, *115*(8), 791.

rather small on the surface, but may have larger cross section areas deeper inside the metal as indicated in **Figure 15**. When the metal corrodes inside the pit, dissolved metal ions generate an environment with a low pH and chloride ions migrate into the pit to balance the positive charge of the metal ions. The environment inside a growing pit gradually becomes more aggressive by the generation of hydrogen ions contributing to the ingress of chloride ions through a lacy cover to maintain the electroneutrality in the pit solution. The repassivation becomes less likely due to the increased aggressiveness in the pit solution and also by the restriction to mix the pit solution to the surroundings by the diffusion barrier of the lacy cover on top of the pit. **Figure 16** shows schematically the

**Figure 15** Pitting corrosion on stainless steel, image from scanning electron microscope, SEM, Outokumpu Stainless, R. Qvarfort.

**Figure 16** Schematic presentation of the pit chemistry and the diffusion restriction due to corrosion product formation and the lacy cover of a stainless steel suffering from pitting corrosion.

pit chemistry and the diffusion restriction due to corrosion product formation and the lack of a protective layer on a stainless steel suffering from pitting corrosion. Since pitting may not be immediately visible from a surface inspection and may indeed be concealed altogether if the propagation occurs inside the pit rather than close to the surface, a pitting attack often remains undiscovered until it causes perforation and leakage.

In order for pitting corrosion to propagate and thrive in stainless steels, a concentrated pit solution is needed, else passivation processes would interrupt active corrosion. This solution is produced inside the pit as a result of the increase in the concentration of the dissolved metal. However, the exact chemistry of the solution inside an active pit is not yet determined. Newman has reviewed the research undertaken in recent years to explain the concept of pitting corrosion in stainless steels.<sup>19</sup> The author simplifies the complexity in the chemical reactions inside the pit by indicating that the low pH level results from a large ionic activity coefficient superimposed on hydrolysis reaction such as

Newman also describes the dependence of active dissolution rate on the concentration of dissolved products inside the pit.<sup>19</sup> Tester and Isaacs associated this anodic dissolution process in the pit by anodic diffusion control across an iron-rich salt film formed in the bottom of the pit.<sup>20</sup> The salt film stabilizes the dissolution process by providing a reservoir of acid but at the same time, it consumes acidity in the interface, leading to passivation when the aggressive solution inside the pit is not maintained. Landolt and Grimm showed further that this diffusion-controlled anodic dissolution process reaction was hindered when the amount of chromium in the steel increased to about 25%.<sup>21</sup>

Donker and Degg showed already in 1927 that, by applying an external potential to an iron anode, a pitting potential corresponds to a large increase in the current passing through an electrochemical cell using a cathode of silver and solutions of various salts.<sup>22</sup> The technique was then used by Brenner to study the passivity of stainless steels.<sup>23</sup> Streicher showed in 1956 that by applying a constant current instead of a potential the number of pits per unit of area found for a specific combination of steel and corrosive solution depends directly on the density of the current passing through the surface of a specimen. He also demonstrated the differences in the extent of pitting at increasing current densities and that the pitting data obtained for a certain stainless steel at one temperature cannot be used to predict the

behavior of other stainless steels or for the same steel at other temperatures.<sup>24</sup>

The pitting potential is characterized by the susceptibility of alloys to a defined environment and has been used extensively to rank different steel grades regarding pitting corrosion resistance in various environments containing halides such as chlorides. Laycock *et al.* recently stated that there was an obvious similarity between the pitting potentials of pits and crevices and related the pitting potential to the transition potential between the two regimes to activation control at lower potentials for metastable pitting, where crevice corrosion commonly occurs and diffusion control at higher potentials, where pitting corrosion occurs.<sup>25</sup>

In Smialowska's review of pitting corrosion, the induction time for pit initiation is referred to as the time required to form the first pit on a passive metal exposed to a solution containing aggressive anions (e.g.,  $\text{Cl}^-$ ).<sup>26</sup> Schwenk showed that this induction time at constant chloride content varies as a function of applied potential.<sup>27</sup> The induction time is shorter at a higher applied potential than at a lower potential.

### Critical pitting temperature (CPT)

Brigham and Tozer introduced the postulation of temperature dependence in pitting corrosion in 1973 to use for comparison of a large range of stainless steels with varying pitting corrosion resistance.<sup>28</sup> The authors introduced a method to test pitting corrosion properties in a potential area where temperature showed the main influence on pitting corrosion regardless of the potential. However, later the method was further developed by the introduction of a crevice-free cell by Qvarfort and he showed by polarization measurements that there is a temperature, above which the corrosion is pitting corrosion, but below this temperature pitting corrosion is impossible. This critical pitting temperature was illustrated in dynamic anodic polarization measurements showing a pitting potential above the CPT and transpassive corrosion at higher anodic potentials at a temperature below the CPT. He also showed that the transition between the transpassive corrosion and pitting corrosion was very abrupt at a temperature range  $\pm 1^\circ\text{C}$ .<sup>29</sup> The concept of critical pitting temperature was thereafter developed to measure potentiostatically at 700 mV/SCE in 1 M sodium chloride and it is, at present, widely used as standard (ASTM G 150). The method is used for ranking purposes of higher alloyed stainless steel grades

containing high levels of molybdenum and chromium. Figure 17 illustrates the potential dependence and independency of the CPT.

Newman has summarized the concept of CPT for stainless steel to understand the corrosion of stainless steel by the emphasis on the temperature as the main parameter for pitting corrosion.<sup>19</sup> The CPT is suggested to be the temperature at which passivation occurs simultaneously as the precipitation of an anodic salt film in the pit. The CPT for a specific stainless steel currently refers to the temperature at which passivation reactions intervene in active corrosion. Newman suggests further that two regimes of pit growth can be identified one under mixed activation/ohmic control, which is usually found at lower potentials, and the second under diffusion control, generally at higher potentials with a salt film in the pit bottom.<sup>19</sup> As a lacy cover at the pit mouth develops, it stabilizes the dissolution of the pit, but the dissolution is still metastable at this stage and as pitting corrosion is established, the cover will finally collapse. Repassivation occurs either because of the absence of the salt film or as the lacy cover ruptures. As long as the pit is growing and the salt film is present, the pitting corrosion is under diffusion control. The transition between those two domains is characterized by a transition potential,  $E_T$ . In general, the pitting potential  $E_p$  is the lowest transition potential  $E_T$ , the potential at which stable pitting can be distinguished for a specific stainless alloy and aggressive environment.

Nyman suggests that in order to compare two different stainless steels, for example, S30400 and

S31600 the following relation has to be considered<sup>19</sup>:

$$E_T = E_{\text{corr}} + b_a \log(i_L/i_{\text{corr}}) + \varphi_s$$

where  $E_{\text{corr}}$  and  $i_{\text{corr}}$  are the corrosion potential and corrosion current density, respectively, in the saturated pit solution;  $b_a$  is the anodic Tafel slope;  $i_L$  is the anodic limiting current density; and  $\varphi_s$  is the ohmic potential drop in the pit cavity, which is constant.

When the concentration of the metal cations is at, or slightly above the saturation concentration of metal cations, precipitation of the salt film occurs. In order to precipitate, an anodic current density greater than or equal to the limiting current density, has to flow in the cavity where pitting initiates. The anodic current density required to maintain the local chemistry is then compared with the critical current density for passivation  $i_{\text{crit}}$  from Salinas-Bravo and Newman<sup>30</sup>. For relatively concentrated solutions very clean linear plots of  $E_T$  vs  $\log i_L$  can be generated using artificial pits.

$$I_{\text{crit}}(T, C_s) = nFDC_s/\delta$$

where  $i_{\text{crit}}$  is the critical current density for passivation,  $D$  is the diffusivity of metal ions,  $\delta$  the diffusion length (pit depth),  $C_s$  is the metal ion concentration at the pit surface,  $n$  the charge number, and  $F$  the Faraday's constant.

Salinas-Bravo and Newman also considered that this critical current density exists in the most aggressive pit environment and also considered it to be a steeper function of the temperature than the anodic limiting current density. The concept of CPT was

Figure 17 Potential dependence in transpassive and pitting corrosion.

then concluded to be when the critical current density equals the anodic limiting current density and the temperature at which the salt precipitation is possible.<sup>30</sup> Newman concludes recently, however, that the steeper function of the temperature is trivially true for experiments carried out in strong HCl solution mimicking the pit environment but that there are no precise data available for real pit environments at present.<sup>19</sup>

Moreover, the diffusion length is included in the concept of temperature dependence, which can explain why crevice corrosion appears at lower temperatures than pitting corrosion. Notable is, that the diffusion length in a crevice is generally longer and consequently any CCT, critical crevice corrosion temperature, is lower than CPT for a defined stainless alloy.

**Figure 18** shows a photograph of a stainless steel surface with pitting corrosion after CPT measurement using a crevice-free flush port cell.

Even if the CPT has proved to be a useful value for ranking a wide range of stainless steels with regard to their pitting resistance, it does not necessarily accurately reflect their performance and properties in actual environments. **Figure 19** shows examples of CPT for increasing chromium and molybdenum contents in various stainless steel grades represented by their PRE values. The figure indicates the very strong dependence of corrosion properties on the alloy composition of stainless steels. The difficulties associated with obtaining CPT values for lower

alloyed stainless steels are obvious. Lower alloyed stainless steels such as ferritic stainless steels containing 12% of chromium seem to have CPT values well below room temperature and these steel grades commonly corrode at temperatures of only a few or even below 0°C under these very aggressive conditions.

### 3.04.8.5.3 Crevice corrosion

Crevice corrosion attacks start in a narrow crevice or under a deposit on the stainless steel surface. Cavities, such as those found at flange joints or at threaded connections, are thus often the most critical sites for corrosion of stainless steels.

In narrow crevices, it is possible for a liquid to penetrate into the crevice and cause stagnant conditions by capillary forces. Oxygen and other oxidants are then consumed for the maintenance of the passive layer inside the crevice, the supply of oxygen is after some time restricted, causing a weakened passive layer. Small amounts of dissolved metal ions inside the crevice cause a further decrease of the solution's pH levels and finally, the presence of chlorides facilitates the breakdown of the passive layer. Thus the environment inside the crevice gradually becomes more aggressive and repassivation becomes less likely. As a result, crevice corrosion attacks often propagate at a high rate, thereby causing corrosion failure in a relatively short time.

The mechanisms for under deposit corrosion or crevice corrosion bear several similarities to pitting. However, one of the differences between pitting and crevice corrosion is that pitting initiates at points which are susceptible to corrosion and to which the

**Figure 18** Stainless steel surface with pitting corrosion after CPT measurement in a crevice-free flush port cell.

**Figure 19** Critical pitting temperatures (CPT) measured according to ASTM G 150 for stainless steels with different PRE. All data from surfaces of 320 mesh (Outokumpu Stainless data).

environment has free access. Crevice corrosion, on the other hand, is initiated on the metallic surface where the surrounding solution has restricted access.<sup>15</sup> The rate determining factors in this stage are proposed by Valen to be that the large current density consumes high amounts of oxygen and the narrow crevice, contains less amounts oxygen.<sup>31</sup> Both factors lead to more rapid oxygen depletion inside the crevice. Since oxygen depletion occurs in the crevice or under the deposit the oxygen reduction occurs as cathodic on the outside of the crevice. This causes a potential difference between the inside and the outside of a crevice, which causes the corrosion process to thrive.

Crevice corrosion can be unpredictable and one reason for this is that the critical potential, for crevice corrosion to occur, is dependent on the type of crevice. It is further experimentally more difficult to find universal crevice formers to predict all types of crevice corrosion since the type of crevice found in actual structures may come in many different shapes and forms. Examples of crevice formers are gaskets, flanges joining stainless steel structures, or almost any partial blocking of the stainless surface. It is almost impossible to avoid crevices completely in practical operations, but the principles of good design emphasize that crevices should be kept to a minimum.<sup>32</sup> Figure 20, shows crevice corrosion in a flange after exposure in high temperature and high amounts of chlorides exceeding the corrosion resistance of the steel grade.

One important parameter, which influences the risk of crevice corrosion, is the geometry of the crevice. A narrow crevice of a few micrometers in width is typically more prone to crevice corrosion than a

wider crevice, due to the influence of capillary forces in a narrow gap. The practice of draining the crevice area from the stagnant chloride containing solution may further decrease the risk of crevice corrosion.

In the case of deposits, it can be difficult to measure the crevice area, the degree of porosity and consequently the exact influence of this parameter. Dense deposits will cause more severe corrosion attacks compared with a porous deposit, which allows the solution to diffuse from the narrow area between the stainless surface and the deposit.

There are several ways to prevent crevice corrosion and several courses of action may be taken to minimize the risk, for example, selecting gasket materials that are nonporous and do not contain chlorides, since the chlorides can be released to the surrounding solution. However, in areas where crevices cannot be avoided weld-overlaying the sealing surface can be performed using a filler material that is higher alloyed and thus more corrosion resistant than the flange itself. Sharp corners or angles can be sites for collecting dirt or other solids that act like deposits and consequently increase the risk of corrosion under deposits. As regards other types of corrosion, the risk of crevice corrosion attacks decreases as the alloy content increases in the stainless steel, particularly with regard to chromium, molybdenum, and nitrogen. One stainless steel grade can be resistant to localized corrosion on open surfaces but another higher alloyed stainless steel might be used for creviced conditions.

In some cases when crevices cannot be avoided, there are ways of positioning beams, channels, and stiffeners to encourage smooth flow and to avoid the trapping of solids or deposits. If crevice corrosion occurs on a certain steel grade, the material selection process should take this into account and specify a better and more corrosion-resistant stainless steel grade.

**Figure 20** Example of crevice corrosion in a flange.

#### **3.04.8.6 Stress Corrosion Cracking**

A material failure may be accelerated by the combined effect of a corrosion process and mechanical tensile stress. Two examples of such processes are SCC and corrosion fatigue. SCC does not occur if only one of the two conditions is present. For example, tensile stress present in a stainless steel in a noncorrosive environment is unable to cause SCC.

Different manufacturing processes can introduce stresses in the material. Examples of such processes are coarse grinding, forming, and welding. Any machining on the stainless steel surface that

introduces residual stresses, hardening or martensitic transformation can influence the resistance to SCC. Examples of machining operations of this kind are abrasion or machining techniques that involve deep grooves or notches.<sup>33</sup> However, the degree of the impact from machining on SCC properties is not easily evaluated and ranking methods are most commonly used to test any deterioration or improvement in SCC resistance.

The electrochemical potential of the stainless steel in solution has some effect on the risk for SCC. The susceptible potential zones at which SCC can occur for a given alloy/solution with a typical active-passive behavior are shown in **Figure 21**.

Two zones of susceptibility appear at the potential boundaries where the passive film is less stable. In the active-passive potential zone, SCC occurs where the passive film is relatively weak at active potentials almost inadequate forming the film A, and B in **Figure 28**. In the other potential zone C, in the passive potential area, SCC and pitting corrosion are associated in adjacent or overlapping potential ranges. The common example of SCC in the active-passive potential zone (B) is austenitic stainless steel in hot  $\text{MgCl}_2$  solutions. However, a material, which is not susceptible to SCC, will not crack in despite being in the susceptible zones. SCC in the active-potential area is commonly associated with a low pH contributing to the corrosion mechanism and the cracking in the passive-potential area is associated with high amounts of chlorides contributing to localized breakdown of the passive film.

#### 3.04.8.6.1 SCC mechanisms

There are many attempts to explain the SCC by mechanism taking into consideration both the corrosion process and the role of stresses in the material. Sedriks summarizes some of the numerous

**Figure 21** Susceptible zones in the potential area for stainless steels and SCC.

mechanisms and concludes that the lack of agreement as to which mechanisms are operative have lead to a simplistic nomenclature to describe SCC in terms of the environments that cause it. For example, chloride SCC and caustic SCC describe SCC in chloride environment and in caustics respectively. Hydrogen embrittlement describes cracking in environments in which the cracking process is facilitated by the entrance of hydrogen into the metal.<sup>34</sup>

Some general processes were, however, concluded by Sedriks to provide a basis for a classification of SCC mechanisms based on either removal of material by dissolution or by film formation for separation of the material.<sup>34</sup> In the following section are some mechanisms summarized briefly that were chosen by Newman as three testable cracking models that may account for most known cases of SCC in metals: Slip-dissolution, film-induced cleavage, and hydrogen embrittlement.<sup>35</sup>

#### Slip dissolution

This mechanism is mainly used to explain intergranular cracking in ferritic stainless steels in environments where the stainless steel is passive and in sensitized stainless steels. The crack growth in the slip dissolution model is the result of an extremely localized anodic dissolution. Propagation of the cracks occurs as a result of film rupture, dissolution, and repair. The sides of the crack are considered to be protected by a film, an oxide, which is fractured as a result of plastic strain in the metal at the crack tip.

#### Film-induced cleavage

Film-induced cleavage occurs when the crack is going through a face cubic centre metal, fcc, as an austenitic stainless steel, with a very high velocity in a very short time. The stress corrosion crack introduces a brittle crack in the propagation direction, which is then widened by plastic arrests in the metal. The crack propagates in steps by a brittle crack, which is then widened in steps. As the crack goes further into the material the outer cracks get wider and wider.

#### Hydrogen embrittlement model

Hydrogen embrittlement is assisted by the absorption of hydrogen into the material from an aqueous environment. If the acidification from the hydrogen contributes to passive film breakdown in a crack, the absorbed hydrogen can promote cleavage, intergranular separation or a highly localized plastic fracture.<sup>35</sup> Microstructure plays an important role in

hydrogen embrittlement as in the other mechanistic approaches for SCC. In susceptible steel hydrogen enters under both anodic and cathodic conditions.

Hydrogen embrittlement is accounted for in the presence of hydrogen sulfide  $H_2S$  as in oil wells and releasing hydrogen is also commonly assisted with an acid environment in the presence of sulfur adsorption.

#### 3.04.8.6.2 Impact of mechanical stress on corrosion: stress intensity factor and crack rate

Generally, it is considered that decreasing the applied stress on the material increases the time to failure. Threshold stress intensities ( $K_{ISCC}$ ) are often referred to as stress intensity factors below which the rate of cracking in a given environment is very low. The threshold stress intensity factor indicates a level below which stress corrosion cracks will not propagate. Increasing the stress factor above  $K_{ISCC}$  failure will occur.<sup>34</sup> Stress intensity factors are usually derived from laboratory measurements in environments such as boiling magnesium chloride and care has to be taken since these environments do not coincide with real service in different applications. Pre-cracked specimens are used for measurements of the rate of growth as a function of the stress intensity factor at the tip of the crack. The presence of different microstructure phases, for example, in duplex stainless steels, can result in different stress intensity factor, depending on the microstructure. It is also generally considered that the duplex stainless steels have better SCC resistance than the corresponding austenitic stainless steels. Newman attributes these properties to the differences in the stress intensity factor in the different phases as ferritic and austenite in the microstructure. The effect seems to be that one phase is considered to assist to arresting the crack propagation.<sup>35</sup>

Figure 22 shows a schematic representation of the stress intensity factor and crack rate for S31600 cold worked at 25 and 50% in a hot chloride solution.

The plateau in the schematic representation of the stress intensity factor is proposed by Newman to occur due to chemical reactions controlling the crack rate, rather than mechanical properties. These chemical reactions might be dissolution, diffusion or adsorption.

#### 3.04.8.6.3 Chloride-induced SCC

Circumstances where there is a pronounced risk of SCC include evaporative conditions in chloride

solutions on stainless steel grades with low resistance to SCC, such as the austenitic grade S30400 subjected to stresses by manufacturing processes. The chloride content on the surface increases to very high values as a result of the evaporative conditions, causing corrosion to occur. Failure from SCC is very rapid; there are no warning signs before the failure and the corrosion propagates very rapidly, causing the construction to fail in a short time.

The most common type of SCC on austenitic stainless steel is transgranular SCC, which may develop in concentrated chloride-containing environments at elevated temperatures at around or above 50–60°C. The crack propagation is in many cases perpendicular to the introduced tensile stresses and in transgranular stress corrosion, the cracks run across the grains – to be compared with intergranular SCC, where the cracks run in the grain boundaries. Figure 23 shows typical transgranular SCC in austenitic stainless steel.

**Figure 22** Schematic representation of the Stress Intensity factor and crack propagation rate for S31600 cold worked 25 and 50% in a hot chloride solution. Reproduced from Extracted from Dickson, J. I.; Russel, A. J.; Tromans, D. *Can. Met. Q* **1980**, 19, 161.

**Figure 23** Transgranular SCC in an austenitic microstructure.

Another frequently mentioned cause to SCC of stainless steels is the sensitization of the material. Sensitization occurs when stainless steel is submitted to a high temperature treatment for too long a time, which can cause carbide precipitation to occur if the steel's carbon content is too high. By avoiding sensitization and carbide precipitation, the risk of SCC can in many cases be eliminated. Most commercially available modern stainless steels have low carbon content and amounts below 0.05 wt% are seldom sensitized, even in welding operations. For use in hot concentrated nitric acid, the maximum carbon content is proposed not to exceed more than 0.03 wt%. These improved properties not only contribute to higher resistance to cracking but also enhance the steel's intergranular corrosion properties.

Solutions containing chlorides are not the only environments that can cause SCC of stainless steels. Solutions of other halides may also cause cracking. Sensitized 1.4301 (30400) stainless steels are also susceptible to intergranular SCC in steam and water environments, for example, in boiling water reactors if the stress level is sufficiently high.

#### **3.04.8.6.4 Caustic SCC**

Another risk scenario that may give rise to SCC, particularly in low alloy steels, is very alkaline solutions at high temperatures, where the pH values are above 14 at concentrations between 20 and 70 wt% and temperatures above 120°C. Caustic SCC has been of particular interest to some industries, such as chemicals, petrochemicals, and pulp and paper. Sedriks concludes that any heat treatment or sensitization to produce 475°C embrittlement in duplex stainless steels will promote caustic cracking but also that duplex stainless steels generally offer better resistance to cracking in hot caustic solutions.<sup>33</sup>

The alloy compositions of stainless steels influence the cracking of the material and it would appear that alloys including molybdenum have a different ranking in hot alkaline solutions compared with that obtained for other wet chloride-induced corrosion in stainless steels.

#### **3.04.8.6.5 Sulfide stress cracking (SSC) by hydrogen sulfide**

Contaminants, such as hydrogen sulfide, H<sub>2</sub>S, may increase the risk of SCC in stainless steels in chloride containing environments. Hydrogen sulfide exists in oil and gas wells and stainless steels intended for applications in the oil and gas industry are typically

tested for use under these circumstances. The most important environmental aspects of SCC in the sour service environments common in oil and gas production are hydrogen sulfide, H<sub>2</sub>S partial pressure, pH, and the chloride concentrations.

The cathodic reaction in chloride containing hydrogen sulfide solutions is mainly the reduction of hydrogen ions to hydrogen, which may form either as hydrogen gas or dissolve in the metal as hydrogen atoms:

The adsorption of hydrogen sulfide on the surface promotes the hydrogen absorption in iron alloys. The cathodic rate depends on several parameters such as temperature, pH, concentration of weak acids, and the electrochemical potential of the material. The role of the weak acid is to donate hydrogen ions.

Duplex stainless steels are frequently used in the oil and gas industry because of their mechanical properties and corrosion resistance in chloride environments, for example, in subsea components working at high pressures and high temperatures. Some examples are pipelines, flow lines, and pipe work.

#### **3.04.8.6.6 Hydrogen-induced stress cracking (HISC) using cathodic protection**

Martensitic and ferritic microstructures are susceptible to hydrogen embrittlement whereas austenitic stainless steels are much less likely to suffer from this type of cracking. The resistance to SCC can be influenced by cathodic currents applied to stainless steel in wet environments. For example, the super ferritic grade, UNSS44735, is prone to hydrogen embrittlement when polarized to potentials in the range of 0.9–1.4 V/SCE, caused by overprotection at potentials more negative than –0.8 V/SCE, so potential in this range should be avoided.

High strength steels, including many martensitic grades, are susceptible to hydrogen embrittlement. Yield strength seems to be an important factor and cause of hydrogen embrittlement along with the tempering and precipitation hardening of the material.<sup>33</sup>

Subsea duplex stainless steels are usually subjected to cathodic protection since these steels are typically connected to other carbon and low alloy steel structures that are already protected. Overall, duplex stainless steels have an excellent track record in subsea conditions but hydrogen-induced stress cracking is a risk if cathodic protection is applied in sour environments, containing H<sub>2</sub>S. The reported failures under

cathodic protection have been associated with unusually high mechanical loads, an unfavorable microstructure in the base metal, characterized by large grains, intermetallic phases, etc. or a high ferrite content in welds. Lowering the hydrogen sulfide concentration to below  $0.1 \text{ g l}^{-1}$  can reduce the susceptibility to SCC or by reducing the applied stress level to below 60% of the yield stress.

Many tests on hydrogen embrittlement are carried out using cathodic charging in sulfuric acid solutions that contain arsenic. Hydrogen embrittlement occurs if the applied stress is higher than the yield stress and the presence of hydrogen ions recombines in the presence of the poison arsenic compound in sulfuric acid. The presence of molybdenum in ferritic stainless steel can reduce the steel's resistance to hydrogen embrittlement.

#### **3.04.8.6.7 SCC in atmospheric environments**

A number of accidents have occurred where ceilings in swimming pool houses have collapsed due to corrosion, mainly involving 304 type steel grades. For example, in Steenswijk in the Netherlands in 2001, suspended air channels were collapsed due to corrosion. Analysis revealed that the reason for the collapses was SCC and also that it occurred at lower temperatures than expected based on previous experience. Most other reports of SCC related to atmospheric environments have been at temperatures above  $50^\circ\text{C}$  in combination with chlorides under evaporative conditions and not typically at room temperature.

In recent decades, the atmospheric environment in swimming pool houses has changed as modern pool houses use higher water and atmospheric temperatures for convenience. Furthermore, in many cases, dehumidifiers are installed and the pools have higher water agitation and heavier bather loadings. The swimming pool house atmosphere may also be subjected to changes in humidity and temperature during both day and night.

Experience has shown that items of stainless steel furniture and equipment immersed in or washed by pool water do not suffer from corrosion problems.

Chlorine-based disinfectants are used in most swimming pool water in a form of hypochlorous acid,  $\text{HClO}$ , hypochlorite,  $\text{ClO}^-$ , and chlorine,  $\text{Cl}_2$ , independent of the particular disinfection procedure. Assuming the most typical pH level for swimming pools, that is, between 7.2 and 7.4, the concentration of hypochlorite and hypochlorous acid in the pool water is approximately equal and the concentration of chlorine gas is negligible. The amount of free

chlorine in the pool water, that is, the total concentration of hypochlorite, hypochlorous acid, and chlorine, is usually kept at  $0.5\text{--}2 \text{ mg l}^{-1}$ .

Free chlorine reacts with ammonia and amine compounds introduced to the pool water by bathers forming relatively stable intermediate products, chloramines. Chloramines are volatile substances responsible for 'swimming pool smell' and causing most of the eye and nose irritations to pool users. Chlorine seems to be transported to the metal surface from the pool water in the form of volatile chlorine-based chemicals, probably mainly as trichloramines. Chloramines are sufficiently stable to be carried to relatively distant locations and dissolve in condensed water on a metal surface. However, the deposition of chlorine-based chemicals in the form of water aerosol has also to be considered. Regular maintenance, such as routine cleaning with clean water, reduces the risk of corrosion in these environments significantly.<sup>37</sup>

Iversen and Prosek simulated the worst possible conditions in a swimming pool atmospheric environment by exaggerating the concentration of chloride in the surface electrolyte, the level of tensile stress, the temperature, and the relative humidity of the atmosphere in comparison with values reported from real swimming pool environments to simulate extremely severe conditions.<sup>37</sup> The test method they used consisted in applying droplets of saturated magnesium and calcium chloride spots on the top of U-bent samples of eight grades of stainless steel. A part of each of the samples was exposed at  $50^\circ\text{C}$  over saturated water solutions of respective chloride salts to keep the relative humidity at the deliquescence point. The stainless steel grades S30400 (1.4301) and S31600 (1.4404) were susceptible to SCC in the presence of magnesium and calcium chloride deposits at  $50^\circ\text{C}$  and at the deliquescence point. Transgranular cracks were initiated rapidly, probably within the first week of exposure.

No SCC was found on samples of the higher alloyed austenitic stainless steel grades N08904 (1.4539) and S31254 (1.4547). These were completely free of corrosion or suffered from pitting corrosion. **Figure 24** shows SCC on S31600 from laboratory tests exposed with  $\text{MgCl}_2$  spots at  $50^\circ\text{C}$  and at 31% RH for 22 weeks.

Common austenitic stainless steel grades without molybdenum or with a maximum of 3% molybdenum have been recognized to suffer from SCC under the specific conditions that can occur in swimming pool atmospheres. Therefore, these stainless steels should be excluded from being used as safety-relevant fastening components in swimming pool buildings.

**Figure 24** SCC on S31600 (1.4404) from laboratory tests exposed with  $\text{MgCl}_2$  spots at 50 °C and at 31 % RH for 22 weeks. Reproduced from Iversen, A.; Prosek, T. Eurocorr 2007, Freiburg im Breisgau, Germany, 9–13 September, 2007.

It seems that highly corrosion-resistant stainless steels are necessary for the successful and safe application of stainless steels in swimming pool atmospheres in combination with maintenance such as regular cleaning of the stainless steel surfaces.

#### 3.04.8.6.8 SCC of martensitic stainless steels

Martensitic stainless steels such as S41000 are very susceptible to both SCC and hydrogen embrittlement. Martensitic grades are especially susceptible to hydrogen embrittlement in tempered conditions. This susceptibility to hydrogen embrittlement can have an adverse effect on any cathodic protection of martensitic stainless steels in applications such as in seawater. The cathodic protection sets the potential in a risk area, at low negative potentials, for hydrogen embrittlement to occur. Another risk scenario for martensitic stainless steels is grain boundary precipitation caused by tempering, which leads to an increased risk of intergranular SCC. The hardness of the material is often an important factor in the selection of martensitic stainless steels, but comes at a cost, since the mechanical toughness decreases with increasing hardness. This will also influence the stress levels in the material, particularly in welded components.

#### 3.04.8.6.9 SCC of ferritic stainless steels

Ferritic stainless steels are highly resistant to chloride-induced SCC, but even if ferritic grades do not crack under such conditions, their resistance to other types of corrosion, such as localized corrosion and uniform corrosion, is determined by a combination of the alloy composition and the service environment.

High chromium ferritic alloys can suffer from embrittlement under incorrect and prolonged heat treatment often referred to as 475 °C embrittlement. Even though ferritic stainless steels exhibit excellent resistance to stress corrosion in chloride solutions, sensitization or high temperature embrittlement at 475 °C leads to cracking of these grades in a chloride or caustic

solution. Another operation that increases the susceptibility to cracking in ferritic grades is cold work. Alloying elements in ferritic grades identified as causes of SCC include nitrogen, copper, nickel, and carbon. Microstructure effects on increasing cracking properties, are probably related to the reduction of ductility, which occurs where precipitation of carbides and nitrides occur in high temperature embrittlement at 475 °C.<sup>33</sup>

The most common reported cause of sensitization in ferritic stainless steels is high carbon content. Low carbon and nitrogen levels in ferritic stainless steels are beneficial as they improve the toughness of the material and also help prevent the precipitation of carbides and nitrides. Alloying elements that improve the resistance to cracking of ferritic stainless steels are titanium (Ti) and niobium (Nb).

#### 3.04.8.6.10 SCC of austenitic stainless steels

The alloying element nickel has been widely discussed in terms of its contribution to resistance to chloride-induced SCC of austenitic stainless steels in sodium chloride solutions. Copson showed that for low and high levels of nickel in austenitic stainless steels no SCC occurred in boiling magnesium chloride at 154 °C.<sup>38</sup> However, it should be pointed out that these measurements were carried out under conditions that cannot be transferred to any real environment. Nevertheless, Nickel has a beneficial effect and is known to prevent SCC when the nickel content exceeds 30–40 wt%. Very high amounts of nickel as an alloying element are accounted for in nickel-based materials. Any beneficial effect attributable to nickel only is excluded in the ferritic stainless steels as they normally do not contain nickel and are anyway highly resistant to chloride-induced SCC. An increase in the molybdenum content in austenitic stainless steels has produced a significant improvement in the resistance to SCC in sodium chloride solutions. The resistance to SCC generally increases

in line with the PRE number, as the chromium, molybdenum, and nitrogen content is increased in austenitic stainless steels. The super austenitic stainless steels are highly resistant to chloride-induced SCC. One of the reasons for this is that the assisting corrosion reaction to SCC does not initiate as easily in super stainless steels with a high PRE number as in the standard grades S30400 (1.4301) and S31600 (1.4401).

#### **3.04.8.6.11 SCC of duplex stainless steels**

Generally, duplex stainless steels are more resistant to SCC compared with austenitic stainless steels with corresponding PRE values and alloy composition. This is because duplex stainless steels have a two-phase microstructure. An austenite stabilizing alloying element such as nitrogen and nickel does not dissolve easily in the ferritic phase. The effect of the duplex microstructure on the overall material is a two-phase system and a possible reason mentioned in the literature is different stress intensity factors for the two phases.<sup>35</sup> There are also some theoretical considerations suggesting that the SCC process can be arrested by the differences between the two phases and that propagation is, to some extent, hindered between the two phases. However, occurrences of SCC in duplex stainless steels have been reported in strong alkaline solutions at very high temperatures.

#### **3.04.8.7 Corrosion Fatigue**

It is well-documented that material subjected to a cyclic load far below the ultimate tensile stress can fail, due to fatigue. If the metal is simultaneously exposed to a corrosive environment, the failure can take place at low loads and after a short period of time. Contrary to pure mechanical fatigue, there is no fatigue limit in corrosion-assisted fatigue. The fatigue fracture is brittle and the cracks are typically transgranular, as in SCC, but not branched. Fatigue properties of stainless steels can be read in [Section 3.04.4.4](#).

The fatigue strength is sensitive to the service environment and under both cyclic loading and corrosive conditions; the fatigue strength will generally decrease. In many cases there is no pronounced fatigue limit, as observed in air, but a gradual lowering of the fatigue strength with increasing number of load cycles. The more aggressive the corrosive conditions and the lower the loading frequency, the higher the effect of the environment. During very high frequency loads there is little time for the corrosion to act and the fatigue properties of the

material will mostly determine the service life. At lower frequencies the corrosive action is more pronounced and an aggressive environment may also cause corrosion attacks that will act as stress concentrations and thus contribute to a shorter life. There is a clear tendency that duplex stainless steels resist fatigue and corrosion fatigue better than austenitic stainless steels. The reason is a high strength combined with good corrosion resistance.

#### **3.04.8.8 Corrosion on Stainless Steels Related to Welding Procedures**

The procedure of welding changes mechanical properties, the surface geometry, surface appearance, and microstructure in the weld compared with the base material. These changes have an impact on the corrosion properties of the steel grades and have to be accounted for in a construction, welding procedure, the choice of filler material but also by the postweld treatment.

Welding defects, which occur in connection with the welding procedure, can in some cases have an adverse effect on corrosion resistance. The effects of weld defects will depend on the service environment in which the construction or application is placed. Weld defects in mild environments, for example, clean and moist air, do not normally cause any severe corrosion damage, whereas in more aggressive environments, such as those, which might occur in process industry, could lead to more severe damage. One good rule is to aim to eliminate defects and if they occur, to remove them to ensure optimum corrosion resistance of the welded construction.

In most cases where weld defects cause corrosion attacks, the types of corrosion typically seen are localized corrosion, such as pitting and crevice corrosion. Other types of corrosion attacks might be caused by nonproper welding procedures, as previously mentioned. The combination of unsuitable welding procedures and an aggressive environment can give rise to general corrosion, SCC and/or intergranular corrosion.

Defects possibly causing pitting corrosion are local areas of holes, microcrevices, surface pores, crater pores, spatter, slag or any other surface defect, which naturally can be a location for the initiation of pitting corrosion attacks. Crevice corrosion resistance is decreased by any defect that forms a crevice. Examples of such defects are all types of cracks, incomplete penetration or lack of fusion. Service environments causing deposits under service are also a trigger to the initiation of crevice corrosion.

Uniform corrosion may occur in strong acid environments in connection to oxides or defects caused by ignition spark. If a weld is underalloyed compared with the parent metal, the weld could corrode uniformly leaving the parent metal as if the service environment is too aggressive for the filler material used.

SCC is caused by a combination of factors. These include an aggressive environment as well as an elevated temperature in combination with tensile stresses in the surface. Welding can introduce tensile stresses in the material that can initiate SCC if the other two requirements are present. All types of defects known to cause SCC must be avoided, for example, cracks, or heavy undercuts. The presence of oxygen on the root side during gas tungsten welding, TIG or gas metal arc welding, MIG can, if present in the same concentrations as in the service atmosphere, lead to excessive oxidation of the melted metal during welding. The result is a weld with a totally unacceptable geometry combined with an excessive heat tint – thereby leaving the root side with an unacceptably low corrosion resistance. To avoid excessive oxidation, an inert root gas must always be used during welding.

All types of stainless steels ferritic, duplex, and austenitic must be thoroughly cleaned after welding to accomplish sufficient and acceptable corrosion resistance of the weld.

#### **3.04.8.8.1 Ferritic stainless steels**

The weldability of ferritic stainless steels depends on the chemical composition and more specifically on the ratio of alloying elements such as carbon and nitrogen in relation to the chromium content. Precipitation of chromium carbides along grain boundaries should be avoided since this increases the risk of intergranular corrosion. After welding, heat treatment may be necessary to restore the corrosion resistance of these steels. However, a low ratio of  $(C+N)/Cr$  reduces the risk of chromium carbide/nitride precipitation and any intergranular corrosion in connection with welding.<sup>32</sup>

If insufficient gas protection is used during welding, chromium nitrides may form, caused by an uptake of nitrogen from the atmosphere. These precipitates can cause embrittlement and lower the corrosion resistance.

#### **3.04.8.8.2 Duplex stainless steels**

The modern duplex stainless steels have much better welding characteristics than the ferritic stainless steels and require in general no preheating or postweld heat

treatment. However, duplex stainless steels show ferritic microstructure at very high temperatures and too rapid a cooling can conserve this structure. This could lead to the precipitation of nitride or carbide and consequently increase the risk of intergranular corrosion. However, modern duplex stainless steels contain high nitrogen content and low carbon contents, favoring a two-phase structure free from precipitates. The use of fillers with higher Ni-content ensures a weld metal with sufficient austenite level.

#### **3.04.8.8.3 Austenitic stainless steels**

Austenitic stainless steels are generally easy to weld and do normally not require any preheating or postweld heat treatment. Highly alloyed austenitic stainless steels – also known as super austenitic grades – generally have good weldability, but the micro segregation of molybdenum reduces the pitting resistance in the weld deposit. To counter the reduction in pitting resistance, these grades are welded with a nickel-based filler that has been overalloyed with molybdenum. Super austenitic steels should be welded with a minimum of heating. The presence of ferrite might influence the corrosion resistance in the ferrite phase in some specific environments as nitric acid. To rectify this, the use of fully austenitic electrodes and filler are used in some applications, such as the production of urea and acetic acid.

Intergranular corrosion was previously a problem for stainless steels with high carbon content. Nowadays, modern stainless steel manufacturers have no difficulties in maintaining a low carbon content so intergranular corrosion caused by chromium carbide precipitation after the welding of austenitic and duplex stainless steels is no longer a problem.

#### **3.04.8.8.4 Postweld treatment**

The presence of weld oxides can also cause decreased resistance to pitting corrosion.

Heat tint seen on stainless steels after welding is caused by an oxidation of even fairly minor amounts of oxygen at the high welding temperature during welding. The heat tint influences the passive film and the corrosion properties of the passive film negatively adjacent to the weld. Any oxides, tarnish or scale, should be removed by grinding and/or pickling to maintain the localized corrosion resistance of stainless steels. However, in some cases where the environment will lead to general corrosion such as in strong acids, the service environment will remove the oxide scale.

Grinding of the surface produces a more or less rough surface depending on the grit used. Generally,

the finer the surface finish, the better the corrosion resistance, and grinding coarser than grit 80 very often produces a surface with an unacceptably low pitting resistance compared with the pitting resistance actually inherent in the alloy composition. Coarse grinding can introduce tensile stresses in the surface, which increases the risk of SCC if the environment is too corrosive.

#### **3.04.8.9 General Corrosion**

General corrosion occurs uniformly over the stainless steel surface when the passive layer is completely broken down. Anodic and cathodic reactions occur on the same surface and the corrosion rate is similar over the entire surface.

General corrosion is easier to predict from corrosion rates and thinning of the material over time compared with localized corrosion such as pitting, crevice, and SCC. The corrosion rate can be used for lifetime predictions and in material selection, a stainless steel grade is generally chosen for its low corrosion rate. Material with a corrosion rate of less than  $0.1 \text{ mm year}^{-1}$  is generally regarded as being corrosion-proof, whereas a corrosion rate that exceeds  $1.0 \text{ mm year}^{-1}$  means that the material is regarded as unusable in terms of its corrosion resistance. Extensive data are available on the uniform corrosion properties of commercial stainless steels.<sup>32</sup> However, laboratory tests are not strictly comparable with actual service conditions, where the corroding medium often contains impurities. These may in some cases increase corrosion, in others, decrease it. In unfavorable cases, the increase can be very high. The best material advice is based on results obtained from the actual process or service environment concerned.

The uniform corrosion rate is also affected if the acid contains chemicals that are oxidizing or reducing. Reducing impurities, for example, hydrogen sulfide may increase the corrosion rate. An oxidizing acid that has a positive effect at a lower concentration is nitric acid, since this promotes passivation of the stainless steel surface at some concentrations rather than initiating uniform corrosion. Nevertheless, there is a limit to how oxidizing the environment may be from a corrosion point of view. Some exceptions occur in strongly oxidizing solutions such as in hot concentrated nitric acid or in chromic acid. In these environments, molybdenum is an undesirable alloy addition. A hot concentrated nitric acid can dissolve the passive layer and transpassive corrosion may

occur. The mechanism of transpassive corrosion is not similar to uniform corrosion as the passive layer will be oxidized to more soluble species but the consequence is the same, the passive layer breaks down partly or completely and uniform corrosion occurs. As for many other environments, in common mineral acids and organic acids the higher alloyed stainless steel grades containing higher amounts of chromium, nitrogen, and molybdenum are more resistant to uniform corrosion than the lower alloyed stainless steel grades. Severe environments from a general corrosion point of view are high concentrations of hydrochloric or hydrofluoric acid in which the corrosion may propagate at a rate that can be detrimental to a construction.

Severe environments from a general corrosion point of view are those with high concentrations of hydrochloric or hydrofluoric acid in which the corrosion may propagate at a rate that can be detrimental to a construction.

Engineering with stainless steels relies, in many cases, on test results obtained in laboratory measurements. As with other types of corrosion, a number of different methods are used to describe the susceptibility to uniform corrosion. Isocorrosion diagrams are available for a number of stainless steel grades tested in pure chemicals.<sup>32</sup> The test methods introduce activation of the stainless steel to corrosion in between test periods to forward either propagating uniform corrosion or repassivation.

##### **3.04.8.9.1 Sulfuric acid**

When stainless steels are exposed to acids, the aggressivity of the solution is generally related to the level of concentration and general corrosion increases with temperature, but as far as sulfuric acid is concerned, there are some exceptions to this rule, even with regard to the increase in the concentration. At low concentrations and in concentrated sulfuric acid, the aggressiveness towards stainless steels is low and at intermediate concentrations, sulfuric acid causes high uniform corrosion rates.

The isocorrosion line in the diagram shows the limit for use of the specific stainless steel grade. The line, one for each alloy, represents a corrosion rate of  $0.1 \text{ mm year}^{-1}$ . At concentrations or temperatures above this line the corrosion rate is unacceptably high. In other words, above the isocorrosion line, the corrosion rate is too high and below the line, the material is regarded as corrosion-proof. A safety limit is typically adopted to provide materials selection advice well below the line and not on the line.

As can be seen from the isocorrosion diagrams in **Figures 25** and **26** the steel grade N08904 (1.4539) performs better in sulfuric acid at intermediate concentrations than some other stainless steel grades. Increased nickel, molybdenum, and copper content in the steel sustain the uniform corrosion rate in sulfuric acid.

Comparing the corrosion resistance of N08904 in aerated and deaerated sulfuric acid, **Figures 25–27**, show that in the aerated sulfuric acid some increase in the corrosion rates were observed at intermediate concentrations.

**Figure 25** shows, at very high concentrations of sulfuric acid, above 90 wt% and, at temperatures below 30°C, that there is a possibility of using the standard grade of S31600, since the aggressiveness of the highly concentrated sulfuric acid is less for stainless steel compared to intermediate concentrations of sulfuric acid.

To understand the change in the corrosiveness of sulfuric acid solutions, which is higher at intermediate concentrations than at high concentrations, we must look to the hydrogen ion concentration in the sulfuric acid. At intermediate concentrations, the

**Figure 25** Isocorrosion diagram at  $0.1 \text{ mm year}^{-1}$  for some austenitic stainless steels in aerated sulfuric acid. hydrogen ions are able to dissolve into the water more easily than in the higher concentrations since there are minor amounts of water present in the higher concentrations. The ability of sulfuric acid to be either reductive or oxidizing is also affected by the concentration.

#### 3.04.8.9.2 Hydrochloric acid

Hydrochloric acid is one of the most severe mineral acids for stainless steels. Generally, the corrosion resistance in this type of environment increases with increasing alloy content of chromium, molybdenum, and nitrogen. However, stainless steels are only used at low concentrations of this acid and at low temperatures. The isocorrosion diagram, **Figure 28**,

shows that the corrosion rate increases rapidly when the steel is exposed to hydrochloric acid. Care must also be taken in chemicals where the risk of hydrochloric acid production is possible.

The beneficial effect from molybdenum as an alloying element in stainless steel can be seen from the results in the isocorrosion diagram, where S32654, containing approximately 7 wt% of molybdenum, performs better than the other stainless steels containing lower amounts of molybdenum. It should also be pointed out that even if a low general corrosion rate is obtained for a stainless steel in hydrochloric acid, there would still be an increased risk of pitting at moderate temperatures, as well as a risk of SCC at higher temperatures. Hydrochloric acid is the most

**Figure 27** Isocorrosion diagram at  $0.1 \text{ mm year}^{-1}$  for deaerated sulfuric acid. Reproduced from Alfonsson, E.; Arnvig, P.E.; Bergquist, A.; Ivarsson, B.; Iversen, A.; Leffler, B.; Nordström, J.; Olsson, J.; Stenvall, P.; Wallén, B.; Vangeli, P.; Outokumpu Stainless Corrosion Handbook, 9th ed.; Outokumpu Stainless Oy, Sandviken 2004, pp I:8-I:103.

**Figure 28** Isocorrosion diagram at  $0.1 \text{ mm year}^{-1}$  for hydrochloric acid. corrosive mineral acid and when a stainless steel is activated there is little or no chance of repassivation of the material.

### 3.04.8.9.3 Phosphoric acid

Phosphoric acid is used in many industrial processes and the quality of the acid varies in many cases depending on impurities. If oxidizing chemicals are present, passivity can be obtained, and in pure phosphoric acid, many stainless steel grades are capable of existing without any severe corrosion, as shown in the isocorrosion diagram for pure phosphoric acid (see [Figure 29](#)).

Many types of phosphoric acids are used in industrial applications. The common classification of these

is wet-process phosphoric acids (WPA) and usually means that the acid contains impurities in combination with phosphoric acid. Some triggers to increased corrosiveness in technical phosphoric acids are fluorides, chlorides, and bromides. Care has to be taken while using phosphoric acids containing chlorides and at increased temperatures. A temperature change of 50–100°C would cause the corrosion rate to increase more than 10-fold on a typical stainless steel grade such as S31600, even where only low amounts of chlorides are present in the acid. If the chloride content were to increase to values exceeding 500 mg l<sup>-1</sup> (ppm), even the S31600 grade would be unsuitable due to the high corrosion rate at this temperature range (see [Figure 30](#)).

**Figure 29** Isocorrosion diagram at 0.1 mm year<sup>-1</sup> for pure phosphoric acid. Reproduced from Alfonsson, E.; Arnvig, P.E.; Bergquist, A.; Ivarsson, B.; Iversen, A.; Leffler, B.; Nordström, J.; Olsson, J.; Stenvall, P.; Wallén, B.; Vangeli, P.; Outokumpu Stainless Corrosion Handbook, 9th ed.; Outokumpu Stainless Oy, Sandviken 2004, pp 1:8–1:103.

**Figure 30** Corrosion rate for the stainless steel grade S31600 in phosphoric acid containing chlorides. Reproduced from Alfonsson, E.; Arnvig, P.E.; Bergquist, A.; Ivarsson, B.; Iversen, A.; Leffler, B.; Nordström, J.; Olsson, J.; Stenvall, P.; Wallén, B.; Vangeli, P.; Outokumpu Stainless Corrosion Handbook, 9th ed.; Outokumpu Stainless Oy, Sandviken 2004, pp 1:8–1:103.

Fluorides in phosphoric acids may also have an adverse effect on corrosion resistance if the amounts are too high in combination with temperature increase, see [Figure 31](#). The worse conditions, however, are those where there are synergetic effects between chlorides and fluorides in combination with other impurities. In complex WPA that contains different impurities, it is usually advisable to seek additional information and advice from corrosion experts. Examples of WPA can be found in the literature, however, only as examples and in real applications, the amounts of impurities are typically not the same as published.<sup>32</sup>

#### 3.04.8.9.4 Nitric acid

Nitric acid is generally a passivation acid for common austenitic and duplex stainless steels containing 18 wt% chromium at concentrations of 20 wt% and below 100°C. It is used for cleaning and passivation after any alterations in the stainless steel surfaces in different applications. Nitric acid is also one of the chemicals in pickling acids used in the manufacturing of stainless steels. The use of the stainless steel grade S30400 in nitric acid of different concentrations up to 60 wt% and below 100°C is widely adopted. Even ferritic grades containing 13 wt% chromium are resistant to corrosion in nitric acid at concentrations of 20–60 wt% below 40°C.<sup>32</sup> However, in hot nitric acid there is a risk of intergranular corrosion in most stainless steel grades due to the oxidizing power of the solution. Sedrik reviewed that high silicon alloys have been used

for service in concentrated nitric acid solutions and the stainless steel grade 310L has been used for very hot concentrated nitric acid.<sup>34</sup>

#### 3.04.8.9.5 Organic acids

Most organic acids are less aggressive than the mineral acids. However, formic acid is one exception, as this is aggressive to S30400 at intermediate temperatures and concentrations. The temperature plays a significant role in determining the corrosiveness of formic acid and at intermediate concentrations ranging from 25–85 wt% in combination with a high temperature, that is, 100°C, most stainless steels corrode. However, at lower temperatures, most of the stainless steels containing higher amounts of chromium, nitrogen, and molybdenum are resistant to corrosion in formic acid, see [Figure 32](#). Other organic acids such as acetic and lactic acid are less corrosive and the stainless steel grades S30400 and S31600 are resistant to corrosion at most temperatures and concentrations. However, the stainless steel grades S30400 and S31600 corrode at higher temperatures and concentrations close to boiling point in lactic acid solutions, so higher-alloyed stainless steel must be used in such service environments. In acetic acid, S30400 is prone to corrosion at temperatures above 90°C at concentrations above 10 wt% and even to localized corrosion above 70°C at concentrations above 80 wt%. There are many organic chemicals in pure conditions, many of which are not at all corrosive to stainless steels such as S30400 and S31600. Some examples are fatty acids, such as oleic acid, stearic acid

**Figure 31** Corrosion rate for the stainless steel grade S31600 in phosphoric acid containing fluorides. Reproduced from Alfonsson, E.; Arnvig, P.E.; Bergquist, A.; Ivarsson, B.; Iversen, A.; Leffler, B.; Nordström, J.; Olsson, J.; Stenvall, P.; Wallén, B.; Vangeli, P.; Outokumpu Stainless Corrosion Handbook, 9th ed.; Outokumpu Stainless Oy, Sandviken 2004, pp 1:8–1:103.

or ethanol. The S31600 grade can also cope with most concentrations and temperatures of citric acid.

Oxalic acid has two organic acid functional groups and can release two protons per molecule. This acid is more corrosive for standard stainless steel grades such as S30400 and S31600 and is further highly corrosive to titanium, see [Figure 33](#).

#### 3.04.8.9.6 Alkaline solutions

Stainless steels such as S30400 and S31600 are highly resistant in alkaline environments such as sodium hydroxide and potassium hydroxide at lower and

intermediate temperatures at all concentrations, see [Figure 34](#). The tolerance to chloride contamination in sodium and potassium hydroxide is also much higher compared with neutral water solutions. Uniform corrosion tests have shown that resistance was obtained in solutions containing 1–20 wt% sodium chloride in 40 wt% sodium hydroxide solution using activation and at a temperature as high as 80°C.<sup>32</sup> However, at high temperatures above 115°C and at intermediate concentrations above 20 and 70 wt%, stainless steels are prone to SCC in sodium and potassium hydroxide.

### 3.04.8.10 Galvanic Corrosion

Galvanic corrosion may occur when two dissimilar metals are in electrical contact in a conductive solution, an electrolyte. The corrosion rate is dependent on the conductivity of the electrolyte, on the difference in the galvanic series between the metals and also on the surface ratio between the metals. The position of a metal in the galvanic series, at a specific temperature, in a specific electrolyte can be represented as the corrosion potential of the metal,  $E_{\text{corr}}$  or open circuit potential, OCP. For example, in seawater at  $10^\circ\text{C}$ , passive stainless steel is a more noble metal and has a higher corrosion potential in the galvanic series than the less noble mild steel. If a stainless steel construction is in conductive electrical contact with a less noble metal, the less noble metal will corrode at a higher corrosion rate. Furthermore, if the less noble metal has a small surface ratio compared with the more noble metal, the corrosion rate will increase even more.

Two different stainless steel grades in the passive state, coupled in an electrolyte, are quite close in the galvanic series and the risk of galvanic corrosion is less as long as the stainless steels remain in the passive state. If the passivity of one of the steel grades breaks down and corrosion occurs, the corrosion potential thus changes to the stainless steel active corrosion potential and the corrosion rate is influenced by this change between the two materials. Knowledge about the series in the specific environment is necessary to predict galvanic corrosion. The corrosion potential for a stainless steel can vary as the pH level of the

solution changes and if oxidizing or reductive chemicals are present in the solution.

In summary, the following circumstances influence the extent of galvanic corrosion:

- The relative area between the dissimilar metals. A smaller area of the less noble metal suffers from more aggressive corrosion attack. This relation is often referred to as a small anode to a large cathode.
- The magnitude in variation of nobility of the metals. The higher the potential difference between the dissimilar metals in the galvanic series, the higher the galvanic corrosion rates under wet conductive conditions. The solution's electrical conductivity. The worse leading ability of a solution contribute to limited corrosion attack close to the contact area between the two dissimilar metals.
- The corrosion rate of galvanic corrosion is further decreased by the decrease in temperature of the electrolyte.
- The solution's electrical conductivity. A high conductivity, that is, a high leading ability of a solution contributes to increased electron flow from the corrosion reactions and thereby a higher corrosion rate at the contact area between the two dissimilar metals.
- The rate of galvanic corrosion may be decreased by a reduction in the temperature of the electrolyte.

All passive stainless steels are relatively high up in electrochemical potential, compared with other material, whereas, for example, zinc is relatively low down in potential in the galvanic series, see [Figure 35](#).

There are several ways of preventing galvanic corrosion. Painting operations prevent the electrolyte from reaching the contact area. The use of wax or adhesives in narrow crevices prevents the electrolyte from reaching any contact area and thus prevents corrosion. The use of electrochemical knowledge between metals in construction can also prevent the occurrence of galvanic corrosion as well as being used in corrosion protection.

The risk of galvanic corrosion is severe in seawater applications. To predict the risk of galvanic corrosion the comparison of the different corrosion potentials can be utilized. The larger the difference the greater the risk of attack of the less noble component.

### 3.04.8.11 Intergranular Corrosion

Intergranular corrosion occurs as the name indicates along grain boundaries on. This corrosion form is sensitive to high carbon contents in the stainless steel and occurs if chromium carbides are precipitated in between the grains. Precipitation reactions in stainless steels can be read about in [Section 3.04.5](#). A stainless steel, which was heat-treated to conditions for grain boundary precipitations to occur, is referred to as sensitized. Other circumstances for intergranular corrosion to occur are when carbon is diffusing into the surface layer of the solid stainless steel as in carburization. If the stainless steel components are heat treated with oil, plastic tape or other organic substances on the surface or in atmosphere containing carbon monoxide or hydrocarbons there is a risk of carburization and intergranular corrosion as a result.<sup>32</sup> More about carburization can be read in [Section 3.04.5.4](#).

Intergranular corrosion occurs in solutions where the grain boundaries of chromium carbide are activated and the rest of the material is in a passive

condition, which means under strong oxidizing conditions. But it should also be pointed out that a sensitized stainless steel is vulnerable to other forms of corrosion as pitting, crevice corrosion, and SCC.

Measures to increase the resistance of stainless steels to intergranular corrosion caused by chromium carbide precipitations are to perform solution annealing or lowering the carbon content by stabilizing with titanium and niobium.

The addition of titanium or niobium to the steel, so-called stabilization, means that the carbon is bound as titanium or niobium carbides. Since titanium and niobium have a greater tendency to combine with carbon than chromium, this means that carbon is not available to form chromium carbides. The risk of intergranular corrosion is therefore appreciably reduced. There is, however, a disadvantage associated with stabilization. In the area closest to a weld, the temperature during welding can be so high that titanium or niobium carbides are dissolved. There is then a danger that they do not have time to re-precipitate before the material has cooled sufficiently to allow the formation of chromium carbides in the grain boundaries. This leads to so-called knife line attack in which a narrow zone of material very close to the weld suffers intergranular corrosion. Since the carbon level in stabilized steels is often quite high (0.05–0.08 wt%) this can give serious attack.

Nevertheless, a low carbon content in the stainless steel extends the time required for sensitization to occur and modern steel manufacturing methods enable lower carbon contents to provide a considerable decrease of the risk of intergranular corrosion to occur.

The effect of a decrease in the carbon content is most easily illustrated by a time–temperature–sensitization, TTS-diagram, an example of which is shown in [Figure 36](#). The curves in the diagram show the longest time an austenitic steel of type 18Cr–8Ni can be maintained at a given temperature before there is a danger of corrosion. This means that for

**Figure 35** The corrosion potential,  $E_{\text{corr}}$  of stainless steels in flowing seawater at 10°C.<sup>32,39</sup>

**Figure 36** TTS diagram for S30400 steels with different carbon contents. The curves are based on the Strauss test.<sup>40</sup>

standard low-carbon austenitic steels (L-grades) the risk of intergranular corrosion cracking is, from a practical point of view, eliminated. All high-alloyed austenitic and all duplex grades intended for aqueous corrosion service have carbon contents below 0.03 wt % and are consequently 'L-grades.' Due to the low solubility of carbon in ferrite, the carbon content will have to be extremely low in ferritic stainless steels if the risk of intergranular corrosion is to be eliminated. In ferritic stainless steels, stabilizing element and extra low carbon contents are often used to eliminate the risk of intergranular attack after welding or other potentially sensitizing treatments.

The stainless steels are usually delivered in the solution-annealed conditions which is a heating process causing the chromium carbides to dissolve, followed by rapid cooling. Such an operation leaves the carbon in solid solution in the steel. Even if a sensitized structure occurs, solution annealing recovers the stainless steel microstructure.

#### **3.04.8.12 Erosion Corrosion**

In construction systems where a flow of the solution is a part of the process, a sufficiently high rate to avoid deposits or marine growth is of preference. The mechanical impact from a flowing solution in combination of corrosion reaction might raise the risk of erosion corrosion in tubular systems. However, stainless steels commonly provide high tolerance against erosion corrosion in neutral chloride solutions and an optimum of flow rate avoiding erosion corrosion but mitigate deposits beneficial for both corrosion performance and economics of operation.

Erosion corrosion is a form of corrosion, which occurs at high relative metal-liquid velocities. This form of corrosion includes a mechanical wear of corrosion products. In a solution containing solid particles, for example, sand, the corrosion rate is higher. Stainless steels can be attacked if the composition of the steel grade provides unstable passivity in an aggressive solution. Attacks can occur on, for example, pump impellers. The resistance of stainless steels to erosion corrosion is generally increased by the same alloying elements as those, which increase resistance to general corrosion in the solution in question.<sup>40</sup>

#### **3.04.8.13 Common Test Procedures and Standards for Stainless Steels**

The most reliable test method for stainless steel's performance in an environment is the field-testing procedure. A number of stainless steel grades are

then tested in the service environment for a long period of time, a year or longer. However, there are a number of good test methods for ranking purposes of different stainless steel grades and also in some cases used for control purposes of the steel grades. Below are some of the most common test methods presented, used in the laboratory for research purposes and also for the screening of different stainless steel grades. The test methods are commonly based on the type of corrosion expected to occur.

Laboratory methods offer the most efficient way of ranking different stainless steel grades and their resistance to pitting and crevice corrosion. However, care has to be taken while using laboratory results in real environments, and field tests should, in some cases, be carried out to provide information about the optimum stainless steel grade to use. Laboratory tests can, nevertheless, still be very informative since some of the parameters that have the greatest influence on the corrosion properties of stainless steels may be used to simulate the most aggressive conditions, such as the amount of chlorides, temperature, pH levels, type of acid, any oxidizing chemicals, etc. Advice on material selection can then be formulated on the basis of these results.

#### **3.04.8.14 Localized Corrosion Testing of Stainless Steels using Electrochemical Methods**

The most common electrochemical method currently used to demonstrate the passivity and corrosion of standard alloy stainless steels in different solutions is to perform polarization measurements. **Figure 37** shows a schematic polarization curve for a stainless steel suffering from pitting corrosion at anodic potentials where the electrochemical response of active corrosion is a high current density.

The characteristic of pitting and crevice corrosion is the breakdown of the passive film, represented in polarization measurements by the pitting potential,  $E_p$ . The pitting potential can be defined as the potential at which the current density exceeds  $100 \mu\text{A cm}^{-2}$  for more than a minute. The most common polarization measurements show typically spikes in the current density before the breakdown to corrosion, which are referred to as metastable pitting corrosion.

Both the pitting potential  $E_{pr}$  and the repassivation potential,  $E_r$  are dependent on the scan rate. A higher scan rate will influence the chemical equilibrium reactions at the metal surface. If the scan rate is too high the pitting potential increases and the

repassivation potential,  $E_r$ , will typically decrease.<sup>15</sup> The effect of too high a scan rate is independent of the steel grade.<sup>41</sup>

The distinction between localized corrosion, such as pitting and crevice corrosion, and transpassive corrosion in the polarization measurements, is shown by the slope in the polarization measurements in the higher potential area, shown in **Figure 38**. In the case of pitting the increase in current density is much steeper than in the case of transpassive corrosion. Even more pronounced is the difference in the repassivation potential, where in transpassive corrosion this is closer to the transpassive potential,  $E_{tr}$  than for pitting corrosion.

**Figure 38** shows the polarization measurements illustrating transpassive corrosion at higher anodic potentials.

Comparing the pitting potentials, in solutions containing sufficient amounts of sodium chloride can successfully provide a ranking of the standard stainless steel grades S30400, S31600 and low alloy stainless steel grades. However, the test temperature in combination with the aggressiveness of the solution must exceed the critical pitting temperature (CPT) of the tested steel grade for pitting corrosion to occur.

### 3.04.8.15 Different Stainless Steel Grades and their Resistance to Pitting and Crevice Corrosion

Two common methods for determining the critical pitting temperature, CPT, are prescribed in ASTM G 150 and ASTM G 48. The former is an electrochemical method that uses a set potential at 700 mV/

**Figure 37** Schematic polarization diagram of pitting potential,  $E_p$  and repassivation potential,  $E_r$  in a solution containing chlorides.

**Figure 38** Polarization measurements illustrating transpassive corrosion.

SCE in 1 M NaCl as the electrolyte and then screens the temperature from 0°C to the CPT where pitting corrosion of the steel grade propagates in a crevice-free electrochemical cell. This method provides a different CPT than ASTM G 48, which is an immersion test for 24 h in a 6% FeCl<sub>3</sub> solution that produces an oxidizing effect from the chemical solution instead of from a potentiostat. The temperature is then increased in intervals of 2.5°C until pitting corrosion occurs. Both methods show similar ranking properties with regard to the resistance to pitting corrosion among stainless steel grades, but ASTM G 150 offers better reproducibility than ASTM G 48. **Figure 39** shows critical pitting temperatures for higher-alloyed stainless steel grades according to ASTM G150 and **Figure 40** shows CPT according to ASTM G 48. It should be pointed out that these values do not represent exact values for each steel grade but may deviate due to effects from corrosion kinetics for various surfaces, welding or other mechanical treatments, etc.

The drawback of these methods is that it is extremely difficult to measure lower-alloyed stainless steels, such as 12% chromium ferritic stainless steels or austenitic S30400 (1.4301) grades, due to the aggressiveness of the methods. Both environments cause these types of stainless steel grades to corrode almost immediately when exposed. Today, pitting potentials are typically used for ranking lower-alloyed stainless steels in solutions with different

chloride contents. For comparison, pitting potentials are presented for some standard stainless grades, S30400 (1.4301) and S31600 (1.4401), in **Figure 41**.

There are several standardized methods for measuring stainless steels' susceptibility to crevice corrosion. One concept is to measure the critical crevice temperature CCT, using standard crevice formers of the MTI-2 type in a ferric chloride solution, according to a modified ASTM G 48 method, which is very aggressive to crevice corrosion in stainless steels due to the combination of acidity and oxidizing power. The higher-alloyed, more resistant stainless steel grades provide a higher CCT than the lower-alloyed stainless steels, but this method also has the disadvantage of being too aggressive for the lowest-alloyed stainless steel grades, such as the 12% ferritic stainless steels and S30400. This measure is similar to the CPT measurements only if used for ranking purposes and do not really provide data about the actual service environment. **Figure 42** presents some CCT values for higher-alloyed stainless steels. In testing crevice corrosion resistance of stainless steels a crevice former is used. Depending on the type of crevice former different results can be obtained. It can, in many real environments, be very difficult to translate the type of crevice to the laboratory since crevice corrosion is dependent on the pressure from the crevice former, the ability to drainage the solution out from the crevice and also the crevice area. Generally

**Figure 39** CPT according to ASTM G 150; some examples of single measurements for surface 320 grit, for higher alloyed stainless steels.

**Figure 40** CPT according to ASTM G 48E for some stainless steels.

**Figure 41** Pitting potentials,  $E_p$ , for some standard stainless steels, S30400 and S31600, at different temperatures in 0.1 M NaCl. Scan rate  $20 \text{ mV min}^{-1}$  and defined at  $100 \mu\text{A cm}^{-2}$ .

standardized types of crevices are used for comparison of laboratory purposes. [Figure 43](#) shows an example of a crevice former of MTI type with heels.

#### 3.04.8.16 Screening of General Corrosion Properties of Stainless Steel Grades

One frequently used method to screen a stainless steel grade for many acids and to use for ranking purposes is ASTM G 157-98. The original test method was developed by MTI that has issued a number of strictly specified laboratory tests, which

facilitate direct comparison between stainless steel grades. Control alloys supplied by MTI are included in the tests. The stainless steel is considered to be passive and unaffected by corrosion when the corrosion rate is lower than  $0.127 \text{ mm year}^{-1}$  (5 mpy) and in ASTM G157-98 the lowest temperature at this measure is referred to as the critical temperature  $T_c$ .

A screening of the different stainless steel grades shows a clear influence of the alloy composition on the uniform corrosion properties. The super austenitic stainless steel grades S32654, S31254, and N08904 and the super duplex stainless steel grades S32750 and S32205 provide much better resistance to general corrosion compared with the standard grades of type S30400 and S31600, as can be seen in [Figure 44](#).

#### 3.04.8.17 Testing Stress Corrosion Cracking of Stainless Steels in Environments Containing Hydrogen Sulfide Under Acidic Conditions

Tests are adopted for material selection in environments containing hydrogen sulfide under acid conditions. The most internationally prevalent standardized method used for testing in these environments is NACE TM 0177, which employs a 5% NaCl + 0.5%  $\text{CH}_3\text{COOH}$  solution, saturated with  $\text{H}_2\text{S}$  by continuous bubbling after nitrogen de-aeration and a pH of 2.7–2.8. The test specimens are immersed in acidified solutions by the addition of acetic acid

**Figure 42** CCT for higher alloyed stainless steel grades.

**Figure 43** Example of a MTI crevice former with heaters.

containing sodium chloride, which is saturated with hydrogen sulfide at room temperature prior to the test. The solution is also deaerated with nitrogen gas. Some test results obtained for duplex stainless steels tested according to NACE TM 0177 for 720 h are presented in [Table 10](#). Material selections based on this standardized method are included in NACE MR-0175.

#### 3.04.8.18 Laboratory Tests of SCC

Several methods can be used to test resistance to SCC. However, it can be very difficult to translate

**Figure 44** Critical temperatures,  $T_c$ , at  $0.127 \text{ mm year}^{-1}$  for different stainless steel grades in 1% hydrochloric acid containing 0.3%  $\text{FeCl}_3$  additions.

the results of many of these more or less accelerated tests to reflect performance in an actual service environment, particularly in terms of the tensile stresses that can occur in the material. U-bent samples are used for many tests but can lose the introduced stress level in the test sample by test time. Nevertheless, the practice of ranking the results for different stainless steels can, in combination with experience, provide valuable data for the material selection process. One test method used for testing evaporative conditions is the 'Wick-test,' ASTM G-692-71, which was developed to simulate evaporative conditions at  $\sim 100^\circ\text{C}$  in an insulation material wetted with dilute chloride solution. The results obtained from this test for different stainless steel grades after 600 h of exposure are presented in [Table 11](#).

Austenitic stainless steels seems much more prone to SCC in this test compared with the duplex corresponding duplex stainless steel grades.

### 3.04.9 Stainless Steels in Natural Wet Environments

Experience has shown that natural water is considerably more corrosive for stainless steel than artificial water. Nevertheless, to understand the interactions between metal surfaces and microbial life in water, in terms of degradation and corrosion, a multidisciplinary view has to be adopted and there are several definitions used in the field of investigation of the interactions

between microbial life and materials resulting in corrosion and/or deterioration of materials.

Microbially influenced corrosion (MIC) can be referred to as the influence of microorganisms on the kinetics of corrosion processes of metals, caused by microorganisms adhering to the interfaces. A prerequisite for MIC is the presence of microorganisms.

#### 3.04.9.1 Microbially Influenced Corrosion

MIC on stainless steels in natural water is commonly related to an attached biofilm growth on a stainless steel surface. If the conditions favor microbial activity in the water, one of the effects of the adhesion of a biofilm to the stainless steel surface is ennoblement of the open circuit potential OCP or corrosion potential  $E_{\text{corr}}$ . The increase in the potential may cause localized corrosion on stainless steel if it reaches a value exceeding the pitting potential of the steel grade. Cases of MIC on stainless steels have been reported for alloys with relatively low molybdenum content as localized corrosion and deposits were often found at or close to the corrosion sites.<sup>41</sup>

[Figure 45](#) shows typical ennoblement on stainless steels S30400 (1.4301) and S31600 (1.4401) in a natural water containing microorganisms.

Parameters that influence microbial activity on metal surfaces are considered to be:

- temperature
- availability of nutrients

**Table 10** Some test results obtained for duplex stainless steels tested according to NACE TM 0177 for 720 h

Material	$H_2S$ (bar)	Load (% $R_{p0.2}$ )		
		70	95	100
S32205	0.01	No cracking	Not tested	No cracking
S32205	0.1	SCC	Not tested	SCC
S32750, welded tube	0.1	Not tested	No cracking	Not tested
S31254	1	No cracking	Not tested	No cracking

**Table 11** Results from the Wick-test, ASTM G-692-71 for some duplex and austenitic stainless steels after 600 h

Microstructure	Material	Number of tested specimens	Failed due to SCC	PRE
Duplex	S32101	6	0	26
	S32304	6	0	23
	S32205	2	0	35
	S31803	4	1	35
Austenitic	S30400	5	5	17.5
	S31603	4	4	24
	N08904	4	1	36
	S31254	3	0	43

- flow velocity
- pH
- oxygen level
- cleanliness
- toxic effects from chemicals

Biofilms may grow under favorable conditions to such proportions that they can be regarded as deposits and the risk of under deposit corrosion or crevice corrosion increases with the density of the deposits.

From early investigations by Mollica and Trevis of stainless steels immersed in seawater, an increase of the open circuit potential or corrosion potential, to high values ranging from 350 to 450 mV/SCE was observed and attributed to the formation of a biofilm on stainless steel surfaces.<sup>42</sup> These values were also reported by many other investigations and the results appeared to be similar and independent of geographical location or hydrological properties, but sensitive to temperature changes. Mollica and Trevis attributed the ennoblement to an increased rate of the cathodic reaction, which has an effect on the corrosion rate in the propagation stage. Feron investigated the temperature effect and the ennobled potential fell above 40°C.<sup>43</sup>

Another explanation for the mechanism of ennoblement is the action of manganese oxidizing bacteria. Tverberg, Pinnow, and Redmerski reported manganese-rich deposits in combination with corrosion in standard stainless steel grades.<sup>44</sup>

While evaluating and predicting MIC in stainless steels, several parameters that influence local corrosion have to be considered. The ennoblement from

active microorganisms increases the risk of exceeding the pitting potential of the passive layer. However, the pitting potential is dependent on factors such as the alloying elements used in the steel grade, welding procedures, chloride content, nitrate content, and deposits. In addition, while considering the risk of MIC in water passing through different industrial water systems, one must also take into account the fact that the water quality varies with respect to factors such as oxygen content and chloride content.

#### 3.04.9.1.1 Chlorination

The conventional way to prevent biofouling or to reduce its effects is to chlorinate the water. This is normally done by continuously or intermittently, adding a strong hypochlorite solution. High chlorine concentrations may increase the corrosivity of water due to the oxidizing effect imposed on the stainless steel. For this reason, the chlorine addition should be restricted to a minimum. The addition of free chlorine in quantities as low as 0.1 mg l<sup>-1</sup> is just sufficient to prevent the formation of an active biofilm but not enough to increase the potential.

Figure 46 shows an example of the time dependence of the open circuit potential on addition of sodium hypochlorite for stainless steel grade S32205 (1.4462). The efficiency of the hypochlorite addition releasing chlorine in this case is approximately ~14%.

By intermittent chlorination, high potentials are reached during a short chlorination period. After chlorination, the potentials decrease to low values

**Figure 45** Ennoblement of the open circuit potential (OCP) on stainless steel in natural water containing microorganisms.

**Figure 46** Time dependence of the open circuit potential for S32205 at different additions of sodium hypochlorite (NaClO) in 1000 mg l<sup>-1</sup> chloride solution. Reproduced from Tverberg, J.; Pinnow, K.; Redmerski, L. NACE Corrosion, Paper 151, April 23–27, Nevada, 1990.

similar to sterile chloride solutions, before the next chlorination period. If the interval between two chlorination periods is very long, an active biofilm will be formed and the potentials will increase once again after a couple of weeks.

The risk of crevice corrosion initiation is increased by the chlorination but the propagation rate of the crevice attack is reduced if intermittent chlorination is used. Crevice corrosion on type S31600 (1.4401) specimens exposed to, for example, nonchlorinated and chlorinated seawater showed the strongest attack in the nonchlorinated water while intermittent chlorination causes only a minor shallow attack.<sup>32</sup>

### 3.04.9.2 River Waters and Freshwater

#### 3.04.9.2.1 Drinking water<sup>32</sup>

Drinking water may seem a relatively harmless environment from a corrosion point of view, and the common austenitic stainless steels, that is, S30400 (1.4301), S31600 (1.4401), and similar grades are suitable for most equipment used in the production and distribution of potable water, but may in rare circumstances suffer corrosion. Standard grade stainless steels such as S30400 and S31600 are widely used in the manufacture of vessels, piping, and heat exchanger tubing for handling all kinds of freshwater. Four primary environmental parameters must be defined for the serviceability of S30400 and S31600 in freshwater. These are the chloride content of the water, the presence of oxygen or any other strong oxidant, the temperature, and the presence of crevices. If one or more of these environmental parameters exceeds these empirical limits, the possibility of localized corrosion is introduced. In most countries, the chloride concentration is limited in potable water, often to a maximum of 0.250–0.300 g l<sup>-1</sup>. However, chemicals added at various stages in the water plant may contain chlorides, with the result that higher chloride concentrations than those specified for drinking water may occur close to the dosage points of such chemicals.

The corrosiveness of the water increases as its temperature rises. Most countries require the temperature of drinking water to be less than 25°C. In consumer applications, stainless steels may also be used in water heaters and hot water tubing, where the water temperature usually exceeds 60°C. In hot water systems, heat transfer may occur through the wall of a tube or a vessel. In such situations, the corrosion risk will also be influenced by the direction of the heat flux. In systems handling hot water, the risk of SCC must sometimes be considered. In the

case of a hot water tube, where the heat flux direction is from the water to the tube wall, the maximum temperature of the stainless steel wall will be that of the water. For the outside of the tube, there should be no risk of corrosion as long as the surface is dry or just wetted by water without chlorides. However, if the outside is wetted by water containing an appreciable amount of chloride ions, evaporation of the water may result in a concentrated solution that promotes pitting and crevice corrosion that, in turn, may act as starting points for SCC. Examples of this situation are water leaking through a chloride containing thermal isolation, or water leaking to the surface of a tube embedded in wall plaster containing a chloride-rich antifreeze agent. The 1.4301 grade (S30400) is sensitive to this type of SCC even after a short wet period whereas type 1.4401 (S31600) can tolerate such conditions for a longer period than 1.4301 (S30400). However, if the wall temperature is less than 50°C, SCC is not likely to occur in ordinary drinking water systems. Duplex stainless steels such as 1.4361 (S32304) and 2205 (S32205) offer better resistance to SCC than the 1.4301 and 1.4401 grades and should be considered for hot water tubing that might be subject to wetting from the outside.

Several oxidizing chemicals may be added at a water treatment plant and in the distribution system, for example, potassium permanganate for the precipitation of metal ions, iron (III) ions for coagulation, and various chlorine compounds and ozone for disinfection purposes. In the presence of strong oxidants, the corrosion potential of the steel will be polarized in the positive anodic direction and the pitting or crevice corrosion potential may be exceeded. Accordingly, there may be a greater risk of localized corrosion attack close to the points where oxidants are added to the water.

#### 3.04.9.2.2 Freshwater

Freshwaters such as lakes and rivers contain much less amounts of chlorides compared with seawater. The material choice of stainless steels relies, in many cases, on the chemical analysis of the water and the temperature. For example, the stainless steel grade chosen should rely on the chloride content of the water but in some cases there are beneficial effects of, for example, sulfates and nitrates solved in the water. However, no systematic studies are available on how beneficial those effects are but in some cases tentative engineering diagrams are used for the determination of a useful stainless steel. There are, however, circumstances when unexpected pitting

or crevice corrosion occurs in freshwater systems and experiences from real systems can be a guide to material advice. One example of tentative engineering diagrams is presented in [Figure 47](#). A significant decrease in the tolerance to chlorides and temperatures is seen from the tentative engineering diagram when crevice corrosion is a risk compared with a base material without any crevices.

Data from tentative engineering diagrams should be a guidance and also taken with care, since there are a number of factors not included such as the impact of different crevices, other impurities, etc.

### 3.04.9.3 Seawater

As seawater contains high amounts of chlorides (~21 000 ppm), standard stainless steels such as 30400 and 31600 are susceptible to localized corrosion such as pitting and crevice corrosion. In addition, natural seawater contains microorganisms, which under beneficial conditions are able to cause ennoblement of the open circuit potential and thereby impose an oxidizing effect. Typical values found in seawater are 300–350 mV/SCE, reached within 10–20 days of exposure. The ennoblement caused by active microorganisms is independent of stainless steel grade. Where ennoblement occurs in combination with biofouling by microorganisms or barnacles on a stainless steel surface, super austenitic or super duplex stainless steels are often

required to ensure corrosion resistance in seawater, even at low temperatures.

Also in seawater as in other natural waters, the ennoblement is sensitive to temperature and imposes a catalytic effect of the cathode reaction, which causes a high current density in corrosion reactions. Practical experience and numerous corrosion tests have shown that conventional stainless steels are prone to localized corrosion in seawater. Over the last decades a number of highly alloyed steels with excellent corrosion resistance have been introduced into the market. Some of the new steels are being used extensively in seawater applications, especially in the seawater systems on offshore platforms.

A common factor of the super austenitic and super duplex stainless steels is a high content of the alloying elements chromium, molybdenum and, in most cases, nitrogen. Typical compositions of seawater-resistant stainless steels, S31254 (1.4547) and S32750 (1.4410) with different structures are shown in [Table 12](#). The two stainless steels, S31254 (1.4547) and S32750 (1.4410) have approximately the same resistance to crevice and pitting corrosion.

#### 3.04.9.3.1 Material selection

[Figure 48](#) shows up to which approximate temperatures stainless steel can be used in oxygen-saturated, slightly chlorinated water of varying chloride content. The diagram is based on studies of literature,

**Figure 47** Tentative engineering diagram for S30400 and S31600 for different chloride contents and temperatures extracted from Outokumpu Corrosion handbook. Reproduced from Alfonsson, E.; Arnvig, P.E.; Bergquist, A.; Ivarsson, B.; Iversen, A.; Leffler, B.; Nordström, J.; Olsson, J.; Stenvall, P.; Wallén, B.; Vangeli, P.; Outokumpu Stainless Corrosion Handbook, 9th ed.; Outokumpu Stainless Oy, Sandviken 2004, pp 1:8–1:103.

**Table 12** Chemical composition and mechanical strength (min. values) of some seawater-resistant and conventional stainless steels

EN	ASTM	Typical composition (%)						Mechanical properties $N\ mm^{-2}$ (20 °C)		Microstructure
		$C_{max}$	Cr	Ni	Mo	Cu	N	$R_{p0.2}$	$R_m$	
1.4547	S31254	0.020	20	18	6.1	0.7	0.2	300	650	Austenite
1.4410	S32750	0.030	25	7	4	–	0.3	550	800	Duplex
1.4436	S31600	0.050	17.5	11	2.6	–	–	220	510	Austenite

1.4462	S31803	0.030	22	5.7	3.1	–	0.17	480	680	Duplex

**Figure 48** Risk of pitting and crevice corrosion on high alloyed stainless steel in water of different chloride contents or temperatures. Reproduced from Alfonsson, E.; Arnvig, P.E.; Bergquist, A.; Ivarsson, B.; Iversen, A.; Leffler, B.; Nordström, J.; Olsson, J.; Stenvall, P.; Wallén, B.; Vangeli, P.; Outokumpu Stainless Corrosion Handbook, 9th ed.; Outokumpu Stainless Oy, Sandviken 2004, pp 1:8–1:103.

combined with practical experience, but it must be underlined that the resistance of a material is also influenced by factors other than temperature and chloride content. Examples of such factors are weld defects, presence of oxide from welding or other heat treatment, contamination of the steel surface by particles of nonalloyed or low-alloyed steel, pH, microbial activity, and the degree of chlorination. The crevice geometry is normally more difficult in a plate heat exchanger than for flange joints, a deeper and more effective crevice due to the curved contact surface, thereof two boundary lines for crevice corrosion on S31254 (1.4547). It should, however, be noted that the crevice geometry of a flange joint is dependent on the pressure that is obtained while tightening screws and bolts. Therefore, the boundary line for crevice corrosion under ‘normal’ conditions can, in

practice, be similar to that which applies to crevice corrosion for plate heat exchangers.<sup>32</sup>

Data from tentative engineering diagrams should be used as a guidance and also taken with care since there are a number of factors not included such as the impact of different crevices, other impurities etc.

### 3.04.9.3.2 Polluted seawater

In practice, the organisms most dangerous to stainless steels are the sulfate reducing bacteria, which receive their energy, by reducing sulfate ions to hydrogen sulfide while simultaneously oxidizing organic substances. The growth of these bacteria is promoted by anaerobic conditions, which, for instance, exist in bottom sediments containing decomposing organic matter.

Several investigations show that hydrogen sulfide stimulates the anodic reaction in the corrosion process

of stainless steels and consequently increases the corrosion rate. Accordingly, very high levels of hydrogen sulfide lower the pitting potential of a stainless steel and increase the rate of the active corrosion existing in the pit. However, hydrogen sulfide acts reducing on the potential, which lowers the corrosion potential. These low potentials mean that the risk of initiation of crevice and pitting corrosion will decrease.

### 3.04.9.3.3 Cathodic protection and hydrogen embrittlement

Naturally, cathodic protection of seawater-resistant stainless steels is not necessary. However, such steels might be included in a protection system if they are parts of a construction in which other components have to be protected, one example being subsea templates in the offshore industry. Another example can be found in power plant condensers when stainless steel tubes have been roller-expanded into tube sheets made of bronze and brass.

However, examples of intentional protection of stainless steel can be found in offshore flow lines, which are placed on the bottom of the sea to transport corrosive oil and gas from satellite platforms to the main platform. In this case, the environment inside the flow line determines the choice of material and this seldom justifies seawater-resistant steel. Therefore, cathodic protection of the outside of the flow line is often necessary in spite of extensive passive corrosion protection.

In cathodic protection with sacrificial anodes, there are always parts of the object where the potential is more negative than the reversible potential of hydrogen evolution, so significant hydrogen evolution always takes place. Under such circumstances certain alloys may pick up hydrogen and thus suffer embrittlement and cracking. The risk is particularly

high if the material is cold worked and subjected to high mechanical stresses and fatigue loading. The austenitic steel is not influenced by seawater and cathodic protection despite being cold worked to 30%. However, embrittle effect on the duplex steel is under debate. The phenomenon needs further investigation, but caution is recommended if severely cold-worked duplex stainless steels are used in seawater constructions equipped with cathodic protection.

### 3.04.9.3.4 Seawater exposures

One of the largest exposure programme run in Europe, the MAST II programme, studied the effects of biofilm growth and the impact of chloride concentrations from different locations in Europe.<sup>46</sup> In this programme, several commercial stainless steels for marine application were chosen and the electrochemical effects induced by biofilm growth were measured and collected on samples exposed in all European seas, from the Mediterranean to the North Sea. **Table 13** presents a list of the stainless steel grades tested. Potential ennoblement of the stainless steels in the passive state occurred at all marine stations and in all four seasons. The initial corrosion potential and the rate of ennoblement showed significant differences between the sites but the reasons for the varying rates were not explained. The ennoblement was related to the seasons of the year and was strongly dependent on the temperature being less rapid in winter than in the summer for all stations.

The samples were immersed in coastal seawaters adjacent to Trondheim (Norway), Kristineberg (Sweden), Cherbourg (France), Brest (France) and Genoa (Italy).

The main risk of corrosion attack for stainless steels in seawater where there is heavy biofouling is crevice corrosion. **Table 14** illustrates the risk of

**Table 13** Stainless steel grades exposed in the MAST II Programme<sup>46</sup>

+ / ++, one/several depassivated areas, no weight loss; 5/5 crevice corrosion on 5 coupons out of 5.

crevice corrosion for different stainless steels exposed to seawater.

The more-alloyed stainless steel grades either austenitic or duplex grades, appeared to be resistant to crevice corrosion in all marine stations after at least a 6000 h of immersion at ambient temperature. The winter and summer tests lasted 3000 h respectively. Some depassivation as discoloration was observed under the crevice washers on many of the samples but no weight losses were observed.

#### 3.04.9.3.5 Anaerobic seawater environments

The presence or absence of a cathodic reaction can determine the extent of corrosion. Oxygen reduction is not the most natural cathodic reaction in natural waters and by the absence of such a reaction may have a beneficial effect in terms of low or virtually zero oxygen content. Mollica, Montini, Scotto, and Marcenaro investigated three stainless steel grades, EN 1.4016(S43000), 1.4301(S30400), and 1.4401 (S31600) that were exposed in an anaerobic clay environment in seawater at the harbor in Genoa, Italy. The exposure time was six months and the coupons were exposed at six various levels of depth to the waterline, where the first level was just under the waterline. During exposure, the open circuit potentials were measured and weight loss measurements were performed after the test. Analysis of free sulfur and pH was carried out at the different levels of exposure. The pH was 7.6 and the sulfur content varied from 2.65 to 3.15 mol l<sup>-1</sup> in the clay. The OCP for EN 1.4301(304) and 1.4401(S31603) was after 40 days at the potential of  $-500 \pm 10$  mV/SCE without any initiation of local corrosion. The stainless steel grades EN 1.4301 and 1.4401 remained corrosion resistant under anaerobic conditions and their

corrosion potential coincided with the redox potential of the medium, indicating that the level of oxygen determined the open circuit potential, or corrosion potential. However, the less noble grade EN 1.4016 suffered local corrosion at potential levels ranging from  $-500$  and  $-600$  mV/SCE.<sup>47</sup>

These results indicate that in a completely oxygen-free environment, even where there are high amounts of chlorides, there is an electrochemical effect of the oxygen removal that coincides with the cathodic protection of the stainless steel. However, in an anaerobic clay or similar environment, any oxidizing coupling effect of the steel, that is, an oxidizing chemical is added or oxygen is present from another source, causes an increase in the potential which can have an adverse effect on the corrosion resistance of stainless steels.

Mollica and Ventura tested crevice samples of the following stainless steel grades: EN 1.4652 (S31654), EN S31254 (1.4547), EN N08904 (1.4539), ENS31600 (1.4404), and EN S32205 (1.4462) in an anaerobic marine environment and simulated a coupling effect between anaerobic and aerobic environments potentiostatically to simulate the rate of ennoblement found in aerobic conditions.<sup>48</sup> They found that the stainless steels were in the passive state at an open circuit potential close to  $-450$  to  $-500$  mV/SCE, almost independent of the alloy composition. However, the passivity was destroyed by a cathodic polarization at a potential below  $-700$  mV/SCE. An activity peak was observed at the potential range  $-600$  to  $-700$  mV/SCE, independently of alloy composition and tested temperatures. Nevertheless, spontaneous repassivation of activated stainless steels was also observed. The spontaneous initiation of crevice

corrosion attacks in stainless steels in totally anaerobic seawater seemed impossible. However, under oxidizing conditions, localized corrosion such as crevice corrosion was initiated.<sup>48</sup>

### 3.04.10 Stainless Steels Performance in Atmospheric Environments<sup>32</sup>

In architectural applications, that is, wall claddings and decorations, stainless steel is often chosen for its aesthetic qualities, since it can be supplied with a variety of surface finishes, and because of its cost benefits – it is virtually maintenance-free.

In structural applications, stainless steel is used for components within the building and construction industry where the emphasis is more on the strength and ductility of the material. In such cases, superficial staining and minor shallow corrosion are not necessarily a cause for concern as there is seldom any risk of structural or mechanical failure of the component. However, for stainless steel roofing, some superficial staining need not be critical, but any penetrating pitting attack will mean that the material chosen will have failed to serve its purpose.

Whatever the reason for choosing stainless steel for architectural applications, material selection must be based on experience and knowledge of the performance of specific grades in specific circumstances. Figure 49 shows the Sickla bridge constructed in duplex stainless steel. The bridge is located close to Stockholm in Sweden.

**Figure 49** The Sickla bridge, constructed in duplex stainless steel.

#### 3.04.10.1 Types of Atmosphere, Corrosivity, and Material Selection

Outdoor atmospheres were previously divided into four categories:

- rural
- urban
- industrial
- marine

Revisions of standards from the international standardization organization, for example, ISO define corrosivity classes rather than atmospheres. The corrosivity of the different atmospheres are calculated and evaluated by pure metals such as carbon, steel, and zinc. The results and corrosivity of environment have been compared with the performance of stainless steels and Table 15 shows stainless steels performing with corrosion resistance in the different corrosivity classes.

**Table 15** A comparison between corrosivity classes according to ISO 9223 and ISO 12944–2, including appropriate stainless steel grades

ISO	Typical environments	Grades
C 1	Indoor, heated. Outdoor, deserts and arctic areas (rural)	S43000, S30400
C 2	Indoor, nonheated. Outdoor, arid and low pollution (rural)	S43000, S30400
C 3	Indoor, humid, low pollution. Coastal areas with low deposits of salt. Urban and industrialized areas with moderate pollution	S30400, S31600
C 4	Indoor with volatile aggressive chemical compounds, swimming pool buildings. <sup>a</sup> Polluted urban and industrialized atmosphere. Coastal areas with moderate salt deposits	S31600, S32205, N08904, S32750, S31254
C 5	Severely polluted industrial atmospheres with high humidity and marine atmosphere with high degree of salt deposits, splashes	N08904, S31254

<sup>a</sup>Attention must be paid to cold stainless steel surfaces well above the water level where volatile compounds, especially chloramines, can condense and cause a special type of SCC. It has been found that only the most resistant grades, that is, N08904 (1.4539) and S31254 (1.4547), are capable of withstanding such conditions. See the previous section on SCC.

**3.04.10.1.1 Indoor, heated, nonheated. Outdoor, arid, low pollution, deserts and arctic areas (Rural), C1–C2**

A rural atmosphere is characterized by clean air, that is, a low level of pollutants, including airborne chlorides from the sea. Acid rain resulting from emissions of sulfur oxides due to the combustion of fossil fuels at remote power stations does not normally cause any problems for stainless steel as long as there are no chlorides present.

Ferritic grades with 17% chromium, for example, 1.4016 (S43000), can normally be used in this type of atmosphere.

Austenitic steels such as S30400 (1.4301) and similar grades are still very common, but these are often selected for their availability and fabrication aspects rather than for their corrosion resistance. Certain forming operations can be facilitated by the use of austenitic grades.

Ferritic grades have a transition temperature, that is, a temperature below which the material becomes brittle. This does not normally create any problems for thin gauges since the transition occurs at temperatures well below zero (°C). However, this phenomenon cannot be totally neglected in countries with cold winters. Austenitic grades are safer in that respect.

**3.04.10.1.2 Indoor, humid, low pollution. Coastal areas with low deposits of salt. Urban and industrialized areas with moderate pollution, C3**

The use of 1.4301 (304) should be limited to indoor nonpolluted atmospheres as described in [Table 1](#).

Urban and industrial atmospheres normally contain oily exhaust fumes from engines and soot and dust, including metal dust. A fall in temperature during the night may expose the stainless steel surface to a slightly acidic condensate, which in turn may cause staining. However, serious corrosion will never occur provided that the atmosphere is free from chlorides. Metal dust, especially if the source is a steel plant or a mechanical workshop fabricating steel items, can attach itself to stainless steel surfaces and affect both the aesthetic and corrosion resistance properties of the stainless steel surface unless it is cleaned regularly.

Stainless steel is commonly used for architectural applications in major cities, and in such an environment, regular cleaning is recommended if the material has been selected for its aesthetic qualities, particularly if the surface is close to street level.

Grades containing 2–2.5% molybdenum, that is, type S31600 (1.4401) and similar, normally offer adequate corrosion resistance even when used for applications in cities situated close to the sea.

The principles of material selection for industrial areas are virtually the same as those, which apply for major cities. However, in an industrial environment, the staining from nearby metal industries can sometimes be so severe that it is almost impossible to maintain a shiny surface appearance. In such cases, if the aesthetic aspects are a prime consideration in material selection, other materials are to be preferred. If the integrity of a structural component is more important, stainless steel is still an excellent material.

**3.04.10.1.3 Indoor with volatile aggressive chemical compounds, roof parts with mechanical load in swimming pool buildings. Polluted urban and industrialized atmosphere. Coastal areas with moderate salt deposits, C4–C5**

A marine atmosphere is characterized by its location to the sea resulting in airborne and depositing chlorides, either as salt crystals or close to water spray. The distance from the sea is important, as is the geographical location. Temperature and humidity are almost as important as the presence of chloride ions.

Molybdenum alloyed grades of type S31600 (1.4401) or comparable grades are normally specified for a marine atmosphere, regardless of whether the application is a prestigious building in a coastal city or an offshore platform. However, this material has inadequate resistance if used close to the sea in tropical countries with high levels of humidity and high daytime temperatures. Examples include cases of SCC reported from industrial installations along the Arabian Gulf coast and in South East Asia. A duplex grade such as 1.4462 (S32205) is a good alternative in those conditions. This grade has also been used for hand railings along beach promenades in the Canary Islands. For high prestigious buildings situated very close to the sea in such countries, it may be necessary to select a very highly alloyed grade such as 1.4547, S31254 or S32750 (1.4410).

Indoor atmospheres are often, to a certain extent justifiably, neglected. They do not normally contain chlorides and the low relative humidity and high temperature make the risk of condensation almost negligible. The criteria for material selection will, in such circumstances, be the same as for rural atmospheres, that is, either a ferritic grade or S30400

(1.4301) or similar as described earlier. This is also what we face while entering a modern office building, an elevator, or a hamburger bar.

However, there are indoor atmospheres for which serious consideration is warranted prior to the installation of stainless steel, whether stainless steel is chosen for its aesthetic properties or for load carrying structural components.

One such case is swimming pool buildings. In such an environment, the combination of high humidity, relatively high temperatures, and the evaporation of volatile chloramines can create very harsh conditions for stainless steel. Chloramines are formed from nitrogenous compounds such as sweat and urine from bathers, and from chlorine, which is used as a disinfectant. Grade S31600 (1.4401) can normally be used for components intended for use or installation below or just above the water surface, for example, handrails, ladders, stairs, etc., whether they are actually immersed in the water or merely exposed to it in the form of splashes. For weight-bearing structural components installed well above the surface of the water, sometimes towards the ceiling, more highly alloyed grades such as 1.4439 (N08904) and S31254 (1.4547) should be selected, for example, ceiling wires and wire ropes, strapping and hose clips, and various types of fasteners.

Another harsh indoor atmosphere can be found on industrial sites which handle acids or chlorinated hydrocarbons. These chemicals can evaporate and later condense on cold metal surfaces. Material selection must be based on actual conditions but grades lower alloyed than S31600 (1.4401) should not be considered. It might sometimes be necessary to use grades as highly alloyed as S32205 (1.4462) or, on rare occasions, even S31254 (1.4547).

### **3.04.10.2 Factors Influencing Atmospheric Corrosion on Stainless Steels**

The importance of keeping the surface clean cannot be stressed enough. 'Cleanliness' in this context can either be achieved by regular washing to avoid staining by soot and dust, or by a carefully prepared postweld cleaning procedure to restore the surface after welding.

The surface finish of the steel is another very important parameter, as it not only has a direct influence on the corrosion resistance, but can also determine the efficiency of cleaning operations.

Narrow crevices always involve a potential risk of crevice corrosion but pockets that collect dirt and moisture should also be avoided.

In some cases, when a design prevents postweld cleaning operations or contains crevices that cannot be avoided, it may be advisable to use a more highly alloyed grade than would otherwise have been chosen in normal service conditions.

## **3.04.11 Application Areas of Commercial Significance**

### **3.04.11.1 Domestic – Kitchenware**

The corrosion resistance of stainless steel is an appealing property of items used in domestic cutlery and kitchenware. The stainless steel grade S30400 (1.4301) or similar grades are frequently used and widespread in these applications. It is used in a wide variety of applications, ranging from brewing vessels to kitchen sinks and milk tankers. The deep drawing properties required to produce beer kegs are good for this steel grade. Stainless steels are tolerant to the wide range of temperatures common in cooking and resist thermal shock very well. A stainless steel surface is also easy to clean. The surface finish is important in applications such as domestic cutlery and kitchenware. A rough surface attracts food deposits, promoting an environment in which microorganisms can proliferate, whereas a smooth and easily cleaned surface will prevent this. The European Hygienic Engineering & Design Group provides guidelines on surface finish, recommending  $R_a$  0.8 mm or better, which can easily be achieved with cold-rolled stainless steels. The  $R_a$  value alone, however, is not a reliable indicator of whether the surface will attract solids or deposits. The cleaning procedure becomes even more important on rough surfaces than on smooth surfaces and it is important to establish how easy it is to clean the surface in actual service conditions.

The environments to which domestic cutlery and kitchenware are exposed often vary from very mild, indoor, dry, and less corrosive environments in the living room to warm, wet environments such as those found in kitchens, in which chloride may be present, or even to outdoor environments such as a patio close to the sea or coastal areas. The dry/wet environment in households varies depending on the chloride content in the water, the temperature and, to a large extent, the humidity and the stainless steel chosen must be capable of withstanding such environments. Typical variations are

- chloride contents: 0.020–0.250 g l<sup>-1</sup>
- temperatures: 20–100°C
- relative humidity: 20–100% RH
- cyclic drying and wet variations, as in flush shower, bath etc.

Some examples of corrosive parameters for using table salts and cooking in kitchenware are:

- food deposits in boiling chloride solution (table salt).
- long-term exposure to chloride water, for example, leaving the pasta in the saucepan.
- partly heated water with table salt for a long time
- acids in the food, for example, in jam, juice, rhubarb.

Examples of stainless steel grades used in cutlery blades and kitchens utensils are presented in [Table 16](#). The use of lower-alloyed and standard grade of S30400 (1.4301) are the most common in these applications. It is important to remember that, for certain application areas in a kitchen environment, corrosion might occur if stainless steel grades at the lower end of the scale are selected. An example is the use of the martensitic grade 1.4006 (410), which provides a sharp edge but is not really a suitably corrosion-resistant steel grade for use in hot chloride water environments.

The main source of corrosion resistance in the stainless steel grades presented in [Table 12](#) is chromium. The lower the chromium content, the lower the corrosion resistance. To test the corrosion resistance of stainless steels used for cutlery, there is an easy and useful test described in EN-ISO8442 – Material and articles in contact with foodstuff. A mild test for the lower end martensitic stainless steels is an immersion test in  $0.050 \text{ g l}^{-1}$  sodium chloride for 6 hours at room temperature, between 18 and  $26^\circ\text{C}$ . Another more aggressive test is EN-ISO8442 – Annex A, part 1 and Annex C part 2, where 1.0 wt% NaCl at  $60^\circ\text{C}$  of cyclic immersion 2–3 times per minutes for 6 h.

### 3.04.11.2 Process Industry

#### 3.04.11.2.1 Hydrometallurgy<sup>32</sup>

Many metals are extracted from mined ores and subsequently refined by hydrometallurgical processes,

which usually involve dissolving of the metals in an acid. Some examples of common hydrometallurgical processes are recovery of zinc, copper, and nickel. These processes vary not only in the sense of corrosive environments but also in process routes. Nevertheless, there are some general operations in the hydrometallurgy processes to recover the desired metals. These stages can include pressure or atmospheric leaching, separation by, for example, solvent extraction or ion exchange. Depending on the desired product the downstream process stages can include purification of solution, product recovery by electrorefining, electrowinning and/or thereafter casting to slabs as, for example, in the zinc production.

Because of its relatively low cost, sulfuric acid is the most important acid used in these processes and it is often produced on-site. Stainless steels are usually the basic materials of construction used for withstanding the acid environment and have several advantages from design and process flexibility point of view. Under the most severe conditions, there are possibilities to identify applications for the super duplex or super austenitic stainless steel grades as well as other steel grades for less severe environments.

The leaching stages have the most demanding environments for stainless steels, since these stages contain not only acid, but also chlorides and metal ions from the ores, concentrate or matte. The presence of metallic ions in combination with chlorides and sulfuric acid complicates the prediction of corrosion of stainless steels in hydrometallurgical process environments. The metal ions, that is,  $\text{Fe}^{2+}/\text{Fe}^{3+}$  and  $\text{Cu}^{2+}$ , have, due to the oxidizing influence, an inhibitive effect on uniform corrosion of stainless steels, when added to sulfuric acid. Conversely, in combination with chlorides this oxidizing effect increases the risk for localized corrosion and too high amounts of chlorides can also lead to increased uniform corrosion. In summary, the combination of sulfuric acid, chloride ions, oxidizing metal ions, and the elevated temperature creates harsh conditions for stainless steels.

**Table 16** Stainless steel grades used in cutlery blades and kitchen utensils

<i>Material</i>		<i>Microstructure</i>	<i>Typical composition (wt%)</i>			<i>PRE</i>
<i>EN</i>	<i>UNS</i>		<i>Cr</i>	<i>Ni</i>	<i>N</i>	
1.4006	S41000	Martensitic	11.5–13.			11.5–13.5
1.4028	S42000	Martensitic	12.0–14.			12–14
1.4016	S43000	Ferritic	16.0–18.0			18–18
1.4301	S30400	Austenitic	17.0–19.5	8.00–10.5	<0.11	17–19.5

**Zinc production**

One of the hydrometallurgical processes used for zinc production is the Jarosite process. This process can be divided into several stages. Neutral leaching is performed in sulfuric acid at a concentration of  $\sim 50\text{--}60\text{ g l}^{-1}$ , that is, at a low pH and a temperature of  $60^\circ\text{C}$ . Oxygen is blown into the process stage from below for further oxidation of the product stream. One stream of the outlets from the neutral leaching stage continues to purification and a separation stage where cadmium, copper, and cobalt are reduced from the product. The other product stream from the neutral leaching stage proceeds to the Jarosite process. The pH in the Jarosite stage is 1.5, containing  $\sim 7\text{--}10\text{ g l}^{-1}$  sulfuric acid. From the Jarosite stage a part of the process solution is recycled to the neutral leaching stage.

A large part of the product stream continues to the hot leaching stage, or concentrate leaching, where Jarosite  $\text{NaFe}_3(\text{SO}_4)_2(\text{OH})_6$  is precipitated. The hot leaching is carried out in tanks made of super-austenitic or super-duplex stainless steels at elevated temperatures of  $\sim 95^\circ\text{C}$ , at chloride contents of  $300\text{--}400\text{ mg l}^{-1}$  and sulfuric acid concentrations of  $60\text{--}80\text{ g l}^{-1}$ . In the hot leaching stage manganese oxide is partly circulated as an oxidizing agent and it can cause deposits on the tanks. Corrosion can occur on grade 1.4539 (N080904) in this very hostile environment while S32750 (1.4410) or S31254 (1.4547) are examples of more corrosion-resistant grades. **Figure 50** shows a tank on the road in S32750 (1.4410) manufactured for a hydrometallurgy process solution.

When cadmium, copper, and cobalt have been removed from the neutral leaching process solution,

**Figure 50** A tank on the road in stainless steel grade S2750 (1.4410).

it continues to the product recovery, the electrowinning stage, where pure zinc is precipitated electrochemically on large cathodes. In this stage manganese dioxide can precipitate on the anode surfaces (lead) causing efficiency loss in due time. For this reason, the manganese dioxide has to be removed. Chlorine can be used, solving the manganese dioxide by oxidation. However, there is an increased risk of localized corrosion on stainless steels, due to the oxidizing effect of chlorine.

The leaching processes in zinc production are under continuous development to increase production efficiency and new processes operate commonly with direct leaching. Zinc concentrate is in the direct leaching process leached in acid slurry at atmospheric conditions by the use of oxygen.

In addition to the hydrometallurgical production of zinc, sulfuric acid is also commonly produced on the site. Before entering the sulfuric acid production, the product stream is filtered electrostatically to remove mercury in a corrosive environment. An example of a steel grade used in the electrostatic precipitator is the super austenitic EN S31254 (1.4547).

**Copper production**

Copper refining is an electrolytic production process using direct current for transporting copper in an electrolyte to large cathodes. The electrolyte has a low pH and contains, for example, copper ions, sulfuric acid, and chlorides.

Copper is precipitated on large cathodes of stainless steels in the electrolytic process. The steel grade used is EN S31600 (1.4404). The high purity copper on the cathodes is then stripped mechanically from the cathodes. The electrolyte might be corrosive for EN 1.4404 when the cathodes are exposed in the solution for longer periods of time when the current is shut off, for example, at maintenance stops, but during operation the cathodes are cathodically protected at low potentials.

**Nickel production**

A very harsh environment for stainless steels can be found in solutions in nickel production using autoclaves at elevated temperatures in combination with chlorides and sulfuric acid. An example of the hostile conditions is the processes operating at a temperature as high as  $250^\circ\text{C}$  and under high pressure. In some of the more demanding environments, metals such as titanium and titanium alloys, zirconium, or even tantalum must be used in the leaching tanks to withstand

the severe conditions. Nonmetallic materials may also be suitable for certain applications in these environments.

#### **Corrosion resistance of stainless steels in simulated hydrometallurgical solutions**

Hydrometallurgical solutions are indeed very complex and in order to document the corrosion properties of stainless steels systematically, the most corrosive parameters have to be considered such as the sulfuric acid, oxidizing chemicals  $\text{Fe}^{2+}/\text{Fe}^{3+}$ ,  $\text{Cu}^{2+}$ , and chlorides and any synergistic effects in between. Laboratory tests have been performed in environments simulating some conditions in hydrometallurgy plants, that is, including chloride ions, ferric ions, cupric ions, and sulfuric acid. Selected temperature was  $98^\circ\text{C}$  and immersion time 30 days. Cold-rolled sheets were used for the preparation of samples, which also were equipped with crevice washers.

Table 17 shows typical compositions of tested stainless grades and Table 18 show the test compounds. Table 19 presents the indications of corrosion resistance in stainless steel grades in these compounds.

Both localized and uniform corrosion occurred simultaneously on the test coupons. In some cases the uniform corrosion was dominating, at very high corrosion rates.

At intermediate chloride contents, between 0.1 and  $0.5 \text{ g l}^{-1}$ , only the super duplex S32750 (1.4410), and super austenitic S31254 (1.4547) were resistant. Severe corrosion occurred while increasing the chloride content above the  $0.5 \text{ g l}^{-1}$  and the temperature was close to the boiling point. Table 20 shows the test results in compounds C and D. Increasing the sulfuric acid content to  $100 \text{ g l}^{-1}$ , but maintaining the low chloride amounts ( $0.1 \text{ g l}^{-1}$ ) did not seem to initiate any corrosion on any of the steel grades, Table 21. These results emphasize the importance on maintaining the chloride levels very low in these very harsh environments.

The corrosion tests were carried out without any activation of the samples during the tests which can have an impact on direct comparison with real service conditions as also other impurities most commonly included in hydrometallurgical service environments.

#### **3.04.11.2.2 Desalination<sup>32</sup>**

Water management will be one of the most important infrastructural tasks for the future to solve all over the world. Desalination, that is, the production of potable water or industrial boiler feed water by removing salt from brackish water, seawater or salty aquifers, involves several stages, each of which places different demands on the construction materials. Figure 51 shows an example of a desalination plant, Melitha.

#### **Multistage flash**

The oldest distillation process, and also the most common for the larger desalination plants, is multistage flash (MSF). In this process, hot deaerated seawater or a seawater/brine mixture at a temperature of around  $110\text{--}115^\circ\text{C}$ , occasionally with some residual chlorine, enters the first stage flash chamber, where some of it evaporates and also condenses. During each stage, the seawater/brine mixture loses some of its energy and the temperature drops far below  $100^\circ\text{C}$  towards the end of the process. However, creating a vacuum, which enables boiling to take place at these low temperatures, counterbalances this. The distillate is achieved by cooling the steam down via numerous condenser tubes running above the flashing seawater.

The most common stainless steel found in MSF plants is S31600 (1.4404), which in the past has been used for the lining of evaporator vessels and for a number of internal components, for example, orifice plates, distillate trays, demisters, and condenser tube support plates. More modern design calls for clad plates in the evaporator vessels, sometimes using S31700 (1.4438). The condenser tubes are mostly

**Table 17** Typical chemical compositions of tested stainless steel grades in weight %

Steel grade, EN	UNS	Cr	Ni	Mo	N	Others
1.4435	31600	17.1	12.7	2.64	0.060	1.5 Cu
1.4539	N08904	19.8	24.0	4.30	0.060	
1.4462	S32205	21.9	5.67	2.99	0.190	
1.4410	S32750	24.7	7.11	3.82	0.280	
1.4547	S31254	20.1	18.1	6.28	0.210	Cu
Hastelloy, C-276		15.3	REM	15.6		
ATi-24						

made of copper alloys, but titanium has also been used. Highly alloyed stainless steel grades, such as S31254 (1.4547) and 1.4565 (S34565) could be an option for the tubes, but neither grade has yet been used for this particular application in MSF plants. However, stainless steel tubes in the S31254 (1.4547) grade have successfully been used for condensers in ventilation systems.

The latest concept for evaporator vessels is solid stainless steel, which has been successfully used for recycling and also once-through plants. Hidd, a 135 000 m<sup>3</sup> day<sup>-1</sup> MSF recycling plant in Bahrain, was commissioned in February 2000 and Melittah, a 15 800 m<sup>3</sup> day<sup>-1</sup> recycling plant in Libya, will start

water production during 2004. The evaporator vessels were made of S31600 (1.4404) and S32205 (1.4462) respectively, and in the latter case the higher strength of 1.4462 (S32205) was used for redesigning the shells, making them around 30% thinner and less costly than if made of S31600 (1.4404).

Solid stainless steel has also been used for once-through plants, that is, MSF with no recycling of brine. The material used for the evaporator vessels must thus resist a very hostile internal environment and also a potentially aggressive external environment, which may include exposure to boiling seawater on a hot wall. Once through implies no deaeration, that is, the water entering the first stage is air saturated with an oxygen level of a few milligrams per liter, and it may contain some residual chlorine.

There are three MSF once-through plants in service in Chile, the oldest was commissioned in 1996, and solid 254 SMO has been used for the first six stages while ASTM 317LMN (1.4439) was used for the remaining six. However, plant tests have shown that 2205 would be a more cost effective alternative than ASTM 317LMN (1.4439) for stages downstream the first six stages. The total capacity of these plants is 10 400 m<sup>3</sup> day<sup>-1</sup>.

**Table 18** Test compounds for immersion tests at 98 °C

Test compound	$Me^{n+}$		$H_2SO_4$ (g l <sup>-1</sup> )	$Cl^-$ (g l <sup>-1</sup> )

**Figure 51** An example of a desalination plant, Melitha.

#### **Low-temperature multieffect, desalination plants (LT-MED)**

One major operational drawback of MSF plants is the formation of scale, calcareous deposits, created by the high temperatures. This has led to the development of LT-MED, where the main deviation is a maximum brine temperature of 55–60°C, as opposed to 110–120°C, resulting in reduced corrosivity towards metallic materials. The physics behind this process are the same as in MSF plants, that is, an applied vacuum causes boiling and evaporation of the incoming seawater at a temperature far below 100°C, but the design of the evaporators and condenser tubes is totally different. There is no flashing but evaporation due to a falling film on tubes where the internal side acts as a condenser while the external side causes boiling.

Different types of material have been used for the evaporator shells; epoxy coated mild steel, clad steel, solid S31600 (1.4404), and even S31254 (1.4547). A duplex grade, such as 1.4462 (S32205), would be an appropriate alternative. A pronounced advantage for a high strength grade such as 1.4462 (S32205) is the cylindrical shape of the LT-MED evaporators making an even more cost-effective design possible than in the case for MSF shells.

There is one LT-MED plant in service with highly alloyed stainless steel condenser tubes, AVR's Demi Water Plant, a 24 000 m<sup>3</sup> day<sup>-1</sup> plant in the Netherlands, where 1.4 million meters of 1.4565 (S34565) tubes were installed.

#### **Reverse osmosis and seawater reverse osmosis**

The reverse osmosis (RO) process is performed at ambient temperature but at a high pressure, for an seawater reverse osmosis (SWRO) plant it is often in

the range 70–80 bar. The feed, seawater or brackish water, is first pretreated, which implies mechanical filtering, chlorination to avoid biofouling, and the addition of chemicals to adjust pH values, etc.

However, the membranes used in RO plants do not tolerate chlorine, so also if the feed has been chlorinated as part of the water treatment, any residual chlorine must be removed prior to the membrane passage, often by an addition of sodium bisulfite or similar. The feed is still air saturated and as the design contains a number of crevices, there is an obvious risk of pitting and, above all, crevice corrosion in these plants.

Highly alloyed austenitic stainless steels, such as S31254 (1.4547), have frequently been used, very successfully, in a number of SWRO plants in the Middle East, on Mediterranean islands, on the Canary Islands, in the West Indies and in the USA. Most of the 'biggest in the world' plants are equipped with high-pressure piping made of S31254 (1.4547) or similar. Materials of type N08904 (1.4539), S32205 (1.4462), 1.4438 (S31700), and 1.4404 (S31600) have previously been used, but the failures have been numerous, not least for 1.4404 (S31600) and 1.4438 (S31700).

Highly alloyed grades have also been used for high-pressure pumps and the super duplex S32750 (1.4410) can be an extremely attractive option for energy recovery systems. The first plant to utilize the properties, that is, strength and corrosion resistance, for the energy recovery system of this grade will be Ashkelon, a 275 000 m<sup>3</sup> day<sup>-1</sup> plant in Israel.

Highly alloyed stainless steels, for example, S31254 (1.4547), can also be used for different filters upstream the high pressure pumps although other materials are often preferred for cost reasons.

#### **3.04.11.2.3 Stainless steel within the pulp and paper industry**

The stainless steel manufacturers have been developing specific stainless steel grades optimized in pulp- and paper process environments. Cost efficiency and sustainability of stainless steels in the pulp- and paper solve corrosion problems. One of the first fields of application for duplex grades was the pulp and paper industry, where the first digesters were mounted in New Zealand in 1988.

Apart from economic factors, a growing concern for the environment has led to a number of new processes being introduced and existing processes being modified. Effluent recycling has also become more common in modern plants. The positive environmental benefits of 'closing-up' the mills have been accompanied by a rise in the concentrations of

chemicals used in process streams, and in operating temperatures. These factors have drastically increased the demands made on the corrosion resistance of the structural materials used in such plants.

Process environments and their impact on corrosion varies in a great extent in different pulp- and paper processes, which also leads to that advice concerning material selection require modification while considering a particular environment at a particular mill.

The duplex alternative, for example, 1.4462 (S32205), is constantly gaining ground at the expense of the other alternatives and many duplex vessels have been started up. The selection of an appropriate duplex grade will, among other things, depend on the process environment in service.

#### 3.04.11.2.4 Architecture – Art <sup>32</sup>

The most visible and perhaps also the most common outdoor applications of stainless steel are for facades, wall claddings, and roofs. The surface finish is selected according to the aesthetic impression required by the architect, whilst the surrounding atmosphere determines the steel grade.

One of the oldest examples of this is the Chrysler Tower in New York, which was crowned with an Art Deco cap of stainless steel as early as 1929. It is still in perfect condition and the extra sheets shipped from Germany during the building's construction and intended for use in future maintenance were still held in storage as recently as 1995. This means that the stainless steel has stood the test of time for more than 70 years without any mass loss or localized corrosion. The steel grade selected was of type 1.4301 (S30200), which would today be regarded as a borderline steel grade in terms of its alloy composition, considering the previous discussion on corrosion hazards. Another equally old landmark is the canopy at London's Savoy Hotel. Both are clearly excellent examples of the understated elegance of stainless steel.

More recent installations that are equally well known are the Court of Human Rights in Strasbourg in France, Canary Wharf in London, and Petronas' 450 m high Twin Towers in Kuala Lumpur, that are all clad with stainless steel of type S31600 (1.4401). The same material was also used for the roof of the new departure terminal at Stockholm's central railway station, built in the late 1980s.

Another recent installation is the Tsing Ma Bridge along the highway to Chep Lap Kok, the new airport of Hong Kong. Whilst this construction is, in some respects, similar to those named earlier, there is an

important difference. In this case, the stainless wind deflectors were not only installed for aesthetic reasons; they are also intended to protect the traffic from strong side winds during the hurricane season.

The elegance of stainless steel can be seen in a number of monuments all over the world. **Figure 52** shows a bridge constructed in stainless steel located at the island Menorca.

The famous Finnish composer Jean Sibelius has been honored with a monument in Helsinki, a stainless steel 'organ,' created by Eila Hiltunen. The same sculptress also created 'The Sun Flower Field,' which was raised in a man-made seawater lagoon outside Jeddah. The selection of steel grade was in both cases based on the respective atmospheres, with type S31600 (1.4436) being selected for the urban atmosphere of the Finnish capital and S31254 (1.4547) for the harsh marine conditions of the Red Sea.

The steel grade S31254 (1.4547) was also used for Carl Milles' sculpture "God and the Rainbow", seen in **Figure 53**, which was inaugurated in 1995 by HRH King Carl XVI Gustaf of Sweden. Its location means that the rainbow is sprayed with water from the Baltic Sea and such conditions would be too harsh for a conventional grade such as S31600 (1.4401).

Maintenance-free structural components can be found in a number of industries, but in selecting a grade for a specific application, it is always important to consider the intended operating environment.

The cable ladders on the Norwegian platform Statfjord A were originally made of painted mild steel, which lasted four years. The replacement ladders made of zinc coated (galvanized) steel lasted another 7 years but were then replaced by stainless steel ladders made of S31600 (1.4401) in 1990.

**Figure 52** Bridge constructed in stainless steel, located at Menorca.

**Figure 53** S31254 (1.4547), used for Carl Milles' sculpture 'God and the Rainbow', seen in [Figure 53](#), which was inaugurated in 1995.

Another example is the internal wall lining of a building for the pickling of steel at a Swedish carbon steel producer. The original lining was made of stainless steel, 1.4436hMo (S31600), which, from an aesthetic point of view, offered inadequate corrosion resistance to the acid condensate precipitated on the walls. The result was heavy rusting and a thorough evaluation of several highly alloyed grades was performed prior to the selection of the wall lining for an expansion in 1998. However, despite the heavy rusting, it was eventually concluded that type 1.4436 was good enough from a functional point of view and this grade was also selected for the expansion.

If similar problems occur at other plants, it is recommended that an exposure test be performed prior to the selection of steel grade.

#### 3.04.11.2.5 *Stainless steel in oil and gas production*<sup>32</sup>

Although oil is not corrosive in itself, production of oil can involve highly corrosive environments because of the simultaneous presence of water and dissolved aggressive species such as oxygen, chlorides, carbon dioxide, and hydrogen sulfide. To a certain degree oil can in fact act as an inhibitor, though it is somewhat unreliable with regard to stainless steels when only a thin oil film is 'isolating' the metal from the corrosive water. Thick films of oil may totally inhibit corrosion.

Initially, mainly carbon steels were used in oil and gas production. However, because of the often increasing amounts of corrosive agents after years of production in old wells and the exploitation of more and more corrosive wells, stainless steels are used increasingly in this industry. Furthermore, environmental considerations have also led to the increased use of stainless steels, since carbon steel demands the addition of vast amounts of various artificial corrosion inhibitors, even under fairly mild corrosive conditions, and most of these inhibitors are more or less hazardous to the environment.

Looking at long term economics, by means of life cycle cost calculations, the use of a stainless steel can often repay the initial extra investment cost, mainly through low maintenance costs and weight savings since stainless steel components do not need to be over dimensioned to compensate for general corrosion, as do carbon steel components. Finally, much longer lifetimes can be achieved with stainless steels than with carbon steels.

#### *Environmental factors*

**'Sweet' or 'sour' environments** Production fluids and gases in the oil and gas industry are traditionally classified as 'sweet' or 'sour' environments, depending on whether hydrogen sulfide is absent or present in significant amounts respectively.

Sweet environments are those containing no or negligible amounts of hydrogen sulfide. High amounts of carbon dioxide may be present in sweet environments, causing accelerated corrosion on carbon steel. Sour environments are those containing significant amounts of hydrogen sulfide. The main concern regarding H<sub>2</sub>S is its ability to embrittle metals thereby causing cracking, 'sulfide stress cracking (SSC),' under certain conditions.

**Hydrogen sulfide** Hydrogen sulfide is one of the main factors to consider, while choosing a material for oil and gas production equipment, because of the risk of SSC.

Sulfides, S<sub>2</sub>, HS or H<sub>2</sub>S adsorbed to the metal surface, catalyze the absorption of hydrogen atoms by the metal, which may subsequently crack due to hydrogen, induced stress cracking (HISC) depending among other factors on the amount of hydrogen absorbed. It is this cracking that is usually termed 'SSC.' The full mechanism of hydrogen embrittlement by H<sub>2</sub>S is still under debate.

The hydrogen absorption caused by H<sub>2</sub>S may work synergistically with the factors involved in

chloride SCC, thereby increasing the risk of environmentally induced cracking.

Hydrogen embrittlement seems to be the most active cracking mode at low temperatures, whereas chloride SCC predominates at high temperatures. Consequently, the combined risk of cracking due to  $H_2S$  and chlorides tends to be most severe for the nonferritic stainless grades at intermediate temperatures, approximately in the range 80–100°C.

When  $H_2S$  is present, it is generally the risk of cracking that is of concern. However, very small amounts of  $H_2S$  should not necessarily be seen as a negative factor since the presence of  $H_2S$  guarantees a low redox potential in the environment and thereby lowers the risk of chloride-induced localized corrosion, for example, SCC, pitting and crevice corrosion.

Actual limiting critical values of  $H_2S$  partial pressures are difficult to give, due to several other factors temperature, pH, and chloride concentration probably being the dominating ones.

**Carbon dioxide** Stainless steels are not susceptible to the general  $CO_2$  corrosion as are carbon steels. For example, pipelines in carbon steel suffering  $CO_2$  corrosion have been replaced with stainless steel and have given very long service lives. However,  $CO_2$  can indirectly affect the performance of stainless steels by dissociation of carbonic acid, which leads to a lowering of pH.

It is not surprising that a higher hydrogen ion activity will increase the driving force for hydrogen being absorbed into the metal, so that the metal becomes more prone to cracking (SSC). A significant hydrogen uptake is, however, still only possible when  $H_2S$  above a certain concentration is present.

It should be borne in mind that most actual systems have natural pH buffering systems such as from bicarbonate present initially. Therefore the full pH lowering effect caused by  $CO_2$  may not be felt because of buffering action. So, in many practical situations, the system may not be as aggressive as expected from the knowledge only of the partial pressures of  $CO_2$  and  $H_2S$ .

**Chlorides** Chlorides are very often present in high concentrations in water associated with oil and gas formations. Localized corrosion on stainless steels induced by chlorides is well-known. However, the

oxygen content of these fluids is mostly extremely low and significantly higher chloride levels are therefore acceptable than under oxygen-saturated conditions. The main cathodic reaction in these systems is the reduction of hydrogen ions.

**Temperature** As is well-known, normally the higher the temperature the more aggressive the environment with regard to localized corrosion induced by chlorides. However, as mentioned earlier, nonferritic stainless steels seem to show their greatest sensitivity to SSC at around 80–100°C in terms of critical partial pressure of  $H_2S$ . This effect is most pronounced in the duplex stainless steels and lower-alloyed austenitic stainless steels. This phenomenon is thought to be explained by the reverse temperature dependency of sulfide-induced SSC and chloride-induced SCC.

**Sulfur** The presence of elemental sulfur has shown to be highly deleterious for stainless steels and may reduce the critical partial pressure of  $H_2S$  appreciably. One possible explanation for the deleterious effect of elemental sulfur is that it can be reduced by hydrogen ions to form  $H_2S$ . However, elemental sulfur does not seem to be present in most wells.

#### **Galvanic effects**

Creating a galvanic contact between stainless steels and carbon steels will often result in full cathodic protection of the stainless steel with regard to chloride-induced localized corrosion. However, ferritic and duplex stainless steels may, during long periods of exposure, develop hydrogen embrittlement from the increase in the cathodic reaction (hydrogen ion reduction) on the stainless steel surface. Obviously this effect is most pronounced at a low pH.

#### **Artificial environments**

In many cases the limiting environment with regard to corrosion may not be the gas or formation water present in the well. A number of chemicals are frequently added to the well in order to optimize the productivity or as part of the initial drilling and set-up procedures.

Stimulation acids are widely used to increase formation permeability. These acids are most often inhibited, however many of these inhibitors have been developed for carbon steel, and there is no guarantee that the inhibition is effective on stainless steels without prior testing.

In general, the use of organic acids is recommended. Excessively large injections should be avoided. This will minimize the risk of creating an unnecessarily aggressive local environment with a low pH. It should be recognized that even though the pH is lowered during acidifying, the concentration of dissolved sulfides is also lowered by general dilution in the near vicinity of the metal.

Completion fluids are sometimes used to counter balance the formation pressure. These fluids may contain high concentrations of chlorides or bromides that inherently introduce an enhanced risk of chloride (halide)-induced localized corrosion.

Injected waters to help secondary recovery may be seawater in the case of offshore production, or produced water in either onshore or offshore production. These waters can be treated in various ways, which influence their corrosivity like dc aeration (less aggressive) or chlorination (more aggressive).

#### **Offshore production – seawater**

Topside equipment may be exposed to seawater internally in the case of seawater being used as a cooling liquid or used for the production of freshwater. The unavoidable splashing from the marine environment causes external exposure of topside equipment to seawater.

In these cases, the selection of a stainless steel grade should be based on the maximum temperature and the condition (aerated and untreated, chlorinated, deaerated, etc.) of the seawater. In the case of splashing from the marine environment, possible evaporative conditions should be considered. The super austenitic 6Mo stainless steel grade S31254 (1.4547) has shown excellent performance in many seawater environments.

Submerged pipelines are another example where the outside environment is sometimes potentially more aggressive than that on the inside.

#### **Metallurgical factors**

It is generally accepted that the sensitivity to hydrogen embrittlement increases with increasing strength. This has led to the practice of specifying a maximum hardness of the material when used in sour service, as in NACE standard MR0175, which is discussed as follows.

It should be recognized that the traditional correlation between strength, hardness, and SSC sensitivity was based on industry experience with carbon steels. The application of this rule is not so straightforward for stainless steels, where the strength in the

annealed condition can vary greatly depending on a number of different metallurgical factors. For example, a high nitrogen content in the fully austenitic stainless steel S31254 (1.4547) or in the super duplex stainless steel S32750 (1.4410) introduces a high strength in the annealed condition, but these steel grades are in general less sensitive to SSC compared with the similar stainless steels containing lower amounts of nitrogen and having lower annealed strength.

Certain stainless steels do, however, become more susceptible to SSC, when they have been cold worked.

**Ferritic and martensitic stainless steels** Ferritic stainless steels are fairly susceptible to SSC, especially in the cold-worked condition. For common ferritic grades the resistance to chloride-induced pitting and crevice corrosion is also limited. Ferritic stainless steels have therefore found limited use in sour production environments.

Martensitic stainless steels are used mainly when high strength is needed in sweet environments, where they have shown to be cost effective in replacing carbon steel suffering from CO<sub>2</sub> corrosion.

Martensitic stainless steels have a fairly limited chloride-induced localized corrosion resistance, and they show a high susceptibility to SSC.

**Austenitic stainless steels** Low-alloyed austenitic stainless steels, types S30400 (1.4301) and S31600 (1.4401), are being used for a large number of components. These alloys are far less prone to SSC than ferritic and martensitic alloys as long as they are in the annealed condition. However, heavy cold work of these alloys does increase their susceptibility to SSC even at ambient temperature. Stainless steel S30400 (1.4301) cold worked 30% exhibits susceptibility to SSC even at very low chloride concentrations.<sup>37</sup>

The super austenitic 6Mo stainless steel grade, S31254 (1.4547) has shown excellent resistance to SSC and SCC. Even after cold work up to 80% and coupled to carbon steel, S31254 (1.4547) is highly resistant to SSC. The carbon steel coupling increases the driving force for hydrogen-induced cracking as discussed earlier.

At high temperatures the high chloride-induced SCC resistance is a further argument for the wide spread use of S31254 (1.4547) in oil and gas production.

**Duplex stainless steels** The high strength of duplex stainless steels together with their high resistance to chloride-induced localized corrosion is

important reasons for their popularity in oil and gas production.

However, it is necessary to observe some restrictions on their use in severe sour environments, since laboratory investigations have indicated moderate SSC susceptibility. It should be borne in mind that pH and stresses in practical applications try tests. This is clearly illustrated by a number of successful applications of duplex steels at far higher partial pressures of  $H_2S$  than a number of laboratory investigations have indicated should be possible.

**SSC test method NACE MR0175** NACE standard MR0175 presents material requirements for resistance to SSC in oil and gas production equipment and related equipment. The document is a broadly written document. Certainly not all materials listed in MR0175 are satisfactory for all practical sour service applications. However, MR0175 is frequently used as a minimum requirement for the selection of materials for sour service.

In this standard a sour gas environment is defined as containing water as a liquid and hydrogen sulfide in the gas at a partial pressure exceeding 3 mbar (0.05 psi), and with total pressures greater than 4.5 bar (65 psi).

In the case of multiphase systems (gas/'oil'/water) MR0175 defines sour environments as systems with  $H_2S$  partial pressure exceeding 3 mbar (0.05 psi) at a total pressure above 18.3 bar (265 psi). At total pressures below 18.3 bar, the partial pressure of  $H_2S$  above 0.7 bar (10 psi) or more than 15%  $H_2S$  also defines a sour environment. Sour multiphase systems that have operated satisfactorily with standard equipment are outside the scope of MR0175.

MR0175 lists a wide range of metallic materials and product forms that under certain conditions are found to be acceptable for use in sour service. In general the main restriction put on the materials is a maximum hardness level. Requirements for welds are generally the same as for the annealed

wrought material with regard to the maximum hardness level.

It should be remembered that MR0175 only addresses SSC in the context of the  $H_2S$  partial pressure, whereas effects of pH and chloride-induced localized corrosion are not taken into account.

### 3.04.11.2.6 *Stainless steel in wastewater treatment* <sup>32,49</sup>

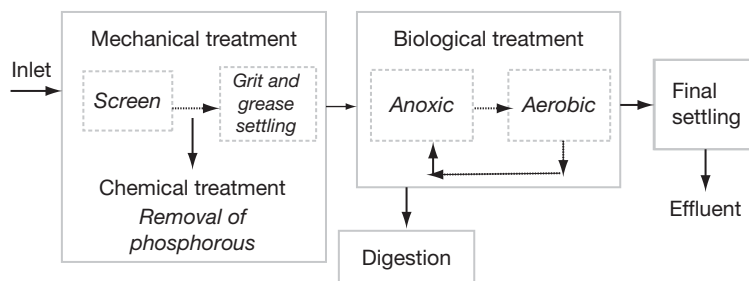

The first methods used to treat wastewater involved reducing the amount of suspended matter in rivers. Biological treatment for further reduction of suspended matter and phosphorus reduction was added as a cleaning process in the 1970s followed by methods for nitrogen removal. During the 1990s, the use of an activated sludge process in the biological treatment of wastewater has increased. New biological purification treatments have been introduced in wastewater treatment plants worldwide, which efficiently reduce nitrates from the water.

#### *Methods of purification*

The design of a wastewater treatment plant will usually depend on what methods are required for purification of the wastewater. Both chemical and biological cleaning processes are used to clean the incoming wastewater.

Wastewater treatment plants may contain several stages involving different processes of purification. Main purification processes are mechanical treatment, chemical treatment with removal of phosphorous, biological treatment (including nitrogen reduction), and removal of organic matter. [Figure 54](#) shows a schematic representation of the main stages in a wastewater treatment plant.

**Mechanical treatment** The sewage enters a wastewater treatment plant through screens that remove

**Figure 54** Schematic view of the main processes in a wastewater treatment plant.

large particles. It then continues to a grit chamber, where grit, gravel, oil, and fat are removed from the wastewater, and thereafter to the primary settling stage.

**Chemical treatment** Phosphorus in wastewater consists of several compounds such as phosphorus in organic compounds and phosphates. However, the organic phosphorus compounds undergo hydrolysis in water and orthophosphate, which is the main compound, is usually removed from the sewage water by precipitation. A variety of precipitation chemicals can be used for this purpose and different plants may have different preferences.

Some examples of precipitation chemicals are ferrous sulfate, aluminum sulfate or iron (III) chloride. In Sweden, the use of poly aluminum chlorides and poly aluminum sulfates in wastewater treatment is a relatively recent development. The dosage point may be prior to the primary settling stage and/or, in some plants, before the final settling tank to ensure low phosphorus content in the effluent.

**Biological treatment** The biological treatment involves both the removal of nitrogen and the removal of biological carbons. In some plants, it may also involve the reduction of phosphorus. This purification process can be divided into several stages. The biological treatment can alternate between anaerobic (anoxic) conditions and aerobic conditions where air is blown into the water. Biological nitrogen is removed in the processes of nitrification and denitrification. An anaerobic environment assists the denitrification process and an aerobic environment assists the nitrification process. During nitrification, ammonia is converted to nitrate, whilst during denitrification, nitrate is converted to free nitrogen. The end product, nitrogen gas, is then released into the atmosphere.

The internal position of the aerobic nitrification and the anaerobic denitrification stages in the biological treatment may vary from plant to plant. In some plants, the aerobic stage may come first, whereas in others, it may occur at the end, followed by recycling to the anaerobic process. Biological carbons are removed during the aerobic stage where nitrification also occurs. During this process, the biological carbons are converted to carbon dioxide and water.

**Final settling** After the biological treatment the wastewater passes on to the final settling tanks where the remaining active sludge settles. The sludge may thereafter be passed back and recycled into the biological treatment or transferred into the

process of digestion. The temperature of the flowing water in the final settling tanks varies commonly between 10 and 15°C. After the final settling stage, the effluent can be released into the sea, lakes, or rivers.

**Digestion** Sludge is removed during the biological treatment and later transferred to large digesters where it undergoes a process of digestion. The active digestion of the sludge is oxygen consuming and the process is considered to be anaerobic. The temperature during the digestion process remains relatively constant at 38°C while the pH level of the sludge can vary between 6 and 8. During biological digestion, biogas containing hydrogen sulfide gas is produced.

The sludge may be dewatered after digestion by centrifugation. If it contains no heavy metals, the dried sludge may be used as fertilizer.

#### ***Corrosion conditions in waste water treatment plants***

**Chloride Content** The chloride ions present in the water promote local corrosion such as crevice corrosion and pitting, and the higher the chloride content, the more corrosive the water. The chloride concentration of the water that passes through sewage treatment plants is usually lower than the chloride concentration of seawater. In Sweden, where the use of de icing salt on the roads is common during the winter period, the chloride content passing through a plant may vary according to season. High values of chloride may be recorded during a few days in the winter season.

**MIC and requirements for localized Corrosion on Stainless Steels** Ennoblement from microbial activity such as, for example, after the biological cleaning stages, that is, in the final settling of a wastewater treatment plant might provide a high potential closer to, or in the vicinity of, the pitting potential for standard stainless steel grades of type S30400 (1.4301) and S31600 (1.4401) under certain conditions such as in the presence of chlorides, crevices, and deposits. In these environments, localized corrosion can be initiated and propagated with an increased corrosion rate due to the enhanced cathodic reaction caused by the microbial activity.

**Addition of Chemicals** The most common chemicals used in Scandinavian wastewater treatment plants to precipitate phosphates are aluminum

sulfate, iron (III) chloride, and iron sulfate. At the point where the dosage is in the plant, there is an increased risk of local corrosion using iron (III) chloride. However, the risk of corrosion on stainless steels declines very fast with the distance to this dosage point since the chemicals are diluted in the flowing water. Less corrosive chemicals with no chloride content are iron sulfate and aluminum sulfate.

If, at any stage of the purification process, any other chemicals are added, for example, strong oxidizing agents such as chlorine as a disinfectant, or potassium permanganate for precipitation reactions, care must be taken with the dosage. The dosage must be low enough to ensure that the effect on stainless steels does not promote any increase in the free corrosion potential. This is essential in both the aerobic and anaerobic stages. The effects of strong oxidizing agents such as chlorine and potassium permanganate are well-documented in [Section 3.04.9](#).

#### **Corrosion results from field tests in wastewater treatment plants**

Field exposures were carried out at different wastewater treatment plants at various locations in Sweden and Denmark to evaluate the risk of corrosion in wastewater treatment plants. The most corrosive part of the plants based on the processes was considered to be the final stages, the settling tanks where chlorides in combination with grown biofilm on the surfaces have to be taken into account. The test materials were welded standard austenitic stainless steel grades S30400, S31600 (1.4301, 1.4436), and a welded duplex stainless steel grade S32205 (1.4462). The chemical compositions of these steels are shown in [Table 21](#). The pitting resistance equivalent (PRE) numbers and the critical pitting temperatures CPT

according to ASTM G 150 for the steel grades are also presented in [Table 22](#).

Field tests were carried out over a 12-month period several wastewater treatment plants in Sweden and Denmark, where the samples were exposed in the final settling tanks. The chemical compositions of the water from three of the exposure sites in the plants are shown in [Table 22](#).

The open circuit potentials were measured in for the test coupons exposed in the plants. From these results it was shown that in aerobic conditions the potential increased to a maximum of 340 mV/SCE, schematically shown in [Figure 55](#), whereas, in more anaerobic conditions the OCP increase was low and even decreased as schematically shown in [Figures 56](#).

At plant 1, corrosion was found on stainless steel grades S30400 (1.4301), and S31600 (1.4436) in combination with heavy deposits, a high chloride content and ennoblement. [Figure 57](#) shows the extent of corrosion on the base material and on the welds of steel grade S31600 after the removal of the deposits containing both sulfur and manganese.

#### **Base material welds**

[Table 23](#) shows the potential values obtained in the field tests in combination with the chloride content and visual observations after the field tests. Biofilms or biological deposits were observed on all samples after the exposure at the plants, but ennoblement was only observed at some plants.

The combination of a high OCP value generated by microbial activity in a biofilm and high chloride content will lead to a higher susceptibility of localized corrosion for steel grade S30400 (1.4301), and S31600 (1.4436). The Localized corrosion was observed in plant 1 for S30400 (1.4301), and S31600

**Table 22** Chemical compositions of treated wastewater from the field-test locations

Compound	Plant 1	Plant 3	Plant 5 (anaerobic)

<sup>a</sup>Oxygen consumption measured as chemical oxygen demand (COD).

<sup>b</sup>Higher value than expected from the anaerobic process.

(1.4436) because of a high OCP and high chloride content in combination with heavy deposits. On the other hand, for plants with a low chloride content in the water, no corrosion was observed.

**Figure 55** Time dependence of OCP during exposure of stainless steels in the final stage of a wastewater treatment plant in Sweden (aerobic biodegradation of wastes in plant 1).

**Figure 56** Time dependence of OCP during exposure of stainless steels in the final stage of a wastewater treatment plant in Sweden (anaerobic biodegradation of wastes in plant 3).

### 3.04.12 High Temperature Corrosion<sup>32</sup>

When stainless steels are exposed to hot gases, chemical reactions take place between the steels, or rather between their alloying elements, and elements or compounds in the gases. As a rule, these reactions will lead to the formation of gas-metal interface layers of reaction products. The chemical compositions and morphologies of these products are determined by, among other factors, the steel and gas compositions and temperatures. These surface layers are more or less protective against further attacks from the gas.

The chemical composition and various standards' designations for some high temperature steels are given in [Table 24](#).

In practice, all stainless steels rely on the formation of an oxide layer. All other reaction products either form a porous, less adherent, and hence nonprotective scale, or are liquid or even volatile and will flux off any existing scale or evaporate. Thus, one condition that must be fulfilled for good high temperature corrosion resistance is that the gas must be oxidizing, that is, it must contain enough oxygen for the formation of a protective layer, consisting of oxides of one or several of the alloying elements. Even so, all oxide scales will eventually experience a breakdown due to growth stresses in the scale. Any measure taken to reduce the scale growth rate will therefore increase the time to breakdown. A low growth rate will also reduce the subscale depletion of the oxide forming element(s), thus improving the ability of the alloy to heal any cracks or other damage to the scale.

The terms oxidizing and reducing are common in the context of high temperature environments, but are not very well-defined and should be used with care. A gas may, for example, be reducing to some of

**Figure 57** Localized corrosion found on S31600 (1.4436) under heavy deposits after a field test at plant 1. (Magnification  $\times 3$ ).

the alloying elements but oxidizing to others. Another gas may contain enough oxygen for the formation of a protective layer; yet at the same time contain other elements that form other, faster growing but less protective compounds.

Gases and/or construction materials are generally chosen to ensure that such a protective layer is in fact formed on the material. For example, the type of gas chosen for heat treatment applications, where oxidation of the treated material is undesired, will generally be reducing, or at least nonoxidizing, to the treated material, but oxidizing to the higher-alloyed furnace construction materials.

In certain processes, however, truly reducing gases are used or produced, and in such circumstances, no oxide layer will form and any existing layer will, as a rule, dissolve. Preoxidation is often used to increase the corrosion resistance in such atmospheres. However, the resulting oxide layer has a limited lifetime and the process of preoxidation has to be repeated at certain intervals.

Heat resistant stainless steels are mainly developed for strength and corrosion resistance at elevated temperatures. As the technical requirements are different, the resistance of these alloys to room temperature 'wet' corrosion may be less satisfactory. The risk of condensation or deposition of aggressive compounds during temporary disturbances or shutdowns

must therefore be considered while selecting the construction material. Alternatively, removal of the aggressive gas may be specified in the service instructions for such events.

Several common corrosion types are described as follows. Since some of these corrosion types are generally active, simultaneously or in sequence, in practical cases, one often has to choose between fulfilling contradictory demands for the material's corrosion resistance. Whilst the mechanical or physical properties of the material may sometimes be paramount, this can to some extent be overcome by design.

The very complex nature of high temperature corrosion and the lack of standardized testing practices make it virtually impossible to present corrosion data in tables.

While choosing material for high temperature applications, one must have an extensive knowledge of existing or expected service conditions, such as gas temperature, gas composition and the temperature of the material. Knowledge of previously used materials, their service performance, and of the cause(s) of previous failures are usually of great support in the process of material selection to identify an optimum high temperature grade.

The demands on the corrosion resistance vary depending on the processes and constructions involved. In some plants, components can be maintained,

repaired, or replaced with minor if any interference to normal service, but in other applications, maintenance and repair must be carefully planned and can only be performed during annual or semiannual shut-downs. Obviously, a more careful choice of materials must be made in those cases.

### 3.04.12.1 Oxidation

When steel is heated in air or another oxygen containing gas, an oxide layer is formed on the surface, acting as a barrier between the steel and the gas. A dense and adherent layer will retard further oxidation, whilst a porous and crack-prone layer will be less protective. Chromium alloyed steels have a better resistance to oxidation than carbon steels since the presence of chromium and mixed chromium-iron oxides in an oxide layer makes it more protective than a pure iron oxides layer. When the chromium content is increased from 0 to 27 wt%, the scaling temperature increases from around 500 to 1125 °C. At temperatures above 1000 °C, aluminum oxides are more protective than chromium oxides. The amount of aluminum required for the formation of a protective layer will, however, make the alloy rather brittle and hence the fabrication difficult and costly.

The scaling temperature is a common measure of the oxidation resistance and is defined as the temperature above which the oxidation rate exceeds a certain value, and is usually determined in different short time cyclic tests, which differ between testing laboratories.

The scaling temperature is primarily used for ranking different alloys. The maximum service temperature in air is usually set some 50 °C lower.

Additions of silicon and rare earth metals (REM) improve the oxidation resistance of steels by reducing the oxide layer growth rate further. The protectiveness of the oxide layer also depends on the oxygen activity of the oxidizing gas, as this affects the morphology and composition of the scale.

Rapid temperature changes are detrimental, since thermal stresses will be induced in the oxide layer due to lower thermal expansion of the oxide relative to that of the base metal. This will eventually lead to cracking and spalling of the layer. Ferritic stainless steels have lower thermal expansion coefficients than austenitic high temperature stainless alloys and are therefore more resistant to oxidation under varying temperature conditions. Unfortunately, this advantage cannot generally be fully exploited at higher temperatures due to the poor mechanical strength and the greater tendency for embrittlement of the ferritic stainless steels. The negative effect of temperature variations on the performance of austenitic alloys can be reduced by several means, for example, by increasing the nickel content. Thereby, satisfactory oxidation resistance up to 1150 °C can be reached. REM additions will lead to the formation of a thinner, more ductile, and hence more adherent oxide layer.

In [Figure 58](#), the oxidation behavior of some common austenitic high temperature stainless steels is compared.

**Figure 58** Comparison between common high temperature steels in oxidation behavior at 1000 °C, 165 h cycles.

Although oxides as a rule are beneficial, there are a few elements which tend to form liquid or even gaseous oxides – especially in stagnant atmospheres – which may lead to “catastrophic oxidation,” that is, fluxing of the scale by the liquid oxide. Molybdenum (Mo), known to be one of these elements, however, is often used to increase wet corrosion resistance, but should be avoided in materials for service at temperatures above 750°C. A similar behavior is reported for tungsten (W). For niobium (Nb), even worse behavior than for Mo and W has been reported, although some sources claim that it can have a positive effect on the oxidation resistance, at least at lower temperatures.

Two other elements, which form liquid oxides, are vanadium and lead. Their concentration in alloys as either alloying or trace elements is too low to be harmful, but they are sometimes present as contaminants in the environment.

### 3.04.12.2 Sulfur Attack

Different sulfur compounds are often present as contaminants in flue gases and some process gases. Chemically, sulfidation is similar to oxidation. However, as a rule, sulfides have lower melting points than the corresponding oxide, so the risk for a fluxing of the scale is greater. Especially nickel is a nonfavorable alloying element in that respect. Moreover, the diffusion rates in sulfide scales are generally much higher than in the corresponding oxides, making the scale growth rate higher and the time to scale breakdown shorter.

In oxidizing gases, that is, when a protective oxide layer can be formed, the corrosion resistance is determined by the properties of that layer. Sulfur attacks generally start at cracks in the layer. A ranking of the corrosion resistance of different materials in oxidizing sulfur-containing environments is often equivalent to the oxidation resistance ranking. On the other hand, under conditions where it is difficult to form a protective oxide layer, the corrosion resistance is considerably lower and directly dependent on the bulk chemical composition of the tested alloys. Under these conditions, steels with high chromium content and little or no nickel are superior.

### 3.04.12.3 Halogen Gas Corrosion

Gases containing halogens, that is, F, Cl, Br, and I or hydrohalides are very aggressive against all metallic materials. Under reducing conditions, nickel and

chromium additions generally improve the corrosion resistance. In oxidizing environments, chromium and especially molybdenum and tungsten are very detrimental due to their tendency to form highly volatile oxychlorides and fluorides.

The halogens of practical interest are fluorine and chlorine. Fluorine is considered to be more corrosive than chlorine, which, on the other hand, is more common and more concentrated in most applications. Although theoretical considerations and laboratory tests yield very low maximum service temperatures (<300°C), in practice, stainless steels can often be used up to 600°C.

Other halogen compounds may be equally corrosive, but only after deposition or condensation, see molten salt corrosion in the following section.

### 3.04.12.4 Molten Salt corrosion

There are several industrial applications in which molten salts are intentionally used, the most important areas being heat treatment, metal extraction, and energy conversion. However, there are also many cases in which the presence of molten salts is far from intentional.

Mixtures of chloride salts are frequently used in salt pots for heat treatment. These ‘neutral salts’ will neither oxidize nor decarburize heat-treated or construction materials when they are pure, but their corrosivity can increase dramatically if they become oxidized or otherwise contaminated. The salt pots often experience localized attacks at the salt–air interface. Salt pot life can be extended by using special inserts at this transition zone, by using an inert gas instead of air, and/or by rectification (deoxidation) of the salt bath. As for chlorine gas corrosion, low-chromium, high- or medium-nickel alloys are the best material choices. Some recent tests have also shown a good performance for low-nickel, high-silicon alloys. In general, however, salt pot failures are due to poor manufacturing, operational, or maintenance procedures, rather than to poor alloy selection.

Fluoride salts have been suggested for use in nuclear power systems. Those mentioned earlier also apply to them.

In the case of hardening salt pots, cyanides are added to the common chloride mixture. The pot material should then be able to withstand carburization and nitridation, that is, high nickel content is beneficial. Since the cyanide keeps the oxygen content at a low level, these salt pots often show longer service lives than ‘neutral salt’ pots.

### 3.04.12.5 Molten Metal Corrosion

Construction materials are deliberately exposed to liquid metals in several applications, for example, heat treatment, energy conversion, and the actual production of those metals. The main corrosion mechanisms in those cases are massive or selective material dissolution, or possibly mass transfer.

Some general observations can be made. With respect to austenitic Ni–Cr–Fe alloys, the higher the nickel content, the more rapidly the alloy dissolves in liquid metal. Ferritic Fe–Cr stainless steels tend to be more resistant, and are not as likely to suffer intergranular attack, as are austenitic alloys.

Specific metals and alloys will not be treated separately in this article. The reader is referred to specialist literature on this subject.

A more unpredictable and hence more dangerous threat is liquid metal embrittlement – a phenomenon caused by local contamination by metals such as Ag, Cu, and Zn. When molten, these metals, or alloys of them, will penetrate austenitic alloys' intergranular and may cause rupture within seconds. Examples where this has been reported to occur are:

- Welding stainless steels to galvanized carbon steels or other zinc contaminated steels, for example, from melting off galvanized steel (e.g., during fire) or from zinc containing paint;
- Weld cracking due to copper contamination, for example, from cold forming tools or back-up bars;
- Cracking caused by copper containing antiseize compounds;
- Cracking from manual, and hence less well-controlled, silver brazing.

**3.05.1 Introduction**

Within the chemical process industry (CPI), as well as other industries, the austenitic corrosion-resistant stainless steels have been, and will continue to be, the most widely used tonnage material after carbon steel. Materials of construction for the modern chemical

process and petrochemical industries must not only resist uniform corrosion caused by various aqueous media, but must also have sufficient resistance to localized corrosion as pitting, crevice corrosion and stress-corrosion cracking. Chemical process and petrochemical industries have to cope with the technical and commercial challenges of rigid environmental regulations, the need to increase the production efficiency by utilizing higher temperatures and pressures and more corrosive catalysts and, at the same time, possess the necessary versatility to handle varied feedstock and upset conditions. Over the past 50 years, improvements in alloy metallurgy, melting technology, and thermomechanical processing, along with a better fundamental understanding of the role of various alloying elements, have led to new nickel alloys that not only extend the range of usefulness of the existing alloys by overcoming their limitations, but are also reliable and cost-effective, and have opened new areas of applications.

Nickel and nickel alloys have useful resistance to a wide variety of aqueous corrosive environments typically encountered in various industrial processes. In many instances, the corrosive conditions are too severe to be handled by other commercially available materials, including stainless and super stainless steels. Nickel by itself is a very versatile corrosion-resistant metal finding many useful applications in industry. More importantly, its metallurgical compatibility over a considerable composition range with a number of other metals as alloying elements has become the basis for many binary, ternary, and other complex nickel alloy systems having unique and specific corrosion-resistant behavior for handling the modern-day corrosive environments of chemical processing, petrochemical, marine, pulp and paper, agrichemicals, oil and gas, energy conversion, and many other industries. These alloys are more expensive than are the standard austenitic corrosion-resistant stainless steels because of their higher alloy content and more involved thermomechanical processing, and hence, are used only when stainless steels are not suitable or when product purity and/or safety considerations are of critical importance. Corrosion resistance depends on the chemical composition of the alloy, the alloy's microstructural features developed during thermomechanical processing, the chemical nature of the environment, and the various reactions occurring at the alloy–environment interface.

In this chapter, the major nickel alloy systems are discussed, including their major characteristics, the effects of alloying elements, and most

importantly, the strengths, weaknesses, and applications of these systems. A few words on fabrication are also included, because an improper fabrication may destroy the corrosion resistance of an otherwise fully satisfactory nickel alloy.

### 3.05.2 Brief Survey of Nickel and Nickel Alloy Groups for Aqueous Corrosive Applications

Nickel and nickel alloy systems for aqueous corrosive applications can be divided into various groups according to their composition as shown in Table 1.

Table 1 gives, in its first column, the internationally used, but not standardized, alloy designation, followed in the second column by the materials' number in use for European standardization (EN). In the third column, the designation according to the unified numbering system (UNS) of the Unified States is indicated. The following columns describe nickel

and the various nickel alloys by means of their main alloying elements, indicating typical values only.

With reference to Table 1 from top to bottom, the first alloy group is unalloyed nickel in its high-carbon (maximum 0.05 mass%) and special low-carbon (maximum 0.02 mass%) forms, designated as alloys 200 and 201, respectively. Second are the nickel–copper alloy 400 and its age-hardenable version alloy K-500, which are widely used. Third is the nickel–molybdenum group, where only one of its members, the quasibinary nickel–molybdenum alloy B-2 is mentioned, due to the very limited use of this type of alloy in special applications. The nickel–chromium alloy group can be considered to be an extension of the austenitic nickel–chromium stainless steels up to very high nickel and to rather low iron content.

The group of nickel–chromium–molybdenum alloys has restricted iron content only and may contain tungsten besides some other elements like niobium, copper, and tantalum. Since the corrosion behavior of these alloys is largely dependent on the amounts of

**Table 1** Principal nickel alloy groups for aqueous corrosive applications

Designation			Main alloying elements, typical values (mass%)					
Alloy	EN	UNS	Ni	Cr	Mo	Cu	Fe	Other elements/remarks
<i>Nickel</i>								
200	2.4066	N02200	99.5					Ni >99.2

chromium and molybdenum being added as alloying elements, the alloys are arranged in **Table 1** according to the sum of these elements in ascending order.

For the same reason, the members of the following nickel–chromium–iron–molybdenum–copper alloy group are arranged according to the sum of their alloying elements chromium and molybdenum in ascending order. However, other alloying elements like copper and nitrogen, and last but not least, nickel, exert an influence on the corrosion behavior too. This will be pointed out more in detail in the following subsection devoted to this alloy group. The alloys of this group are higher in iron than are the alloys of the nickel–chromium–molybdenum alloy group, and are, in this way, closely related to or – depending on the formalities of classification – at the same time part of the corrosion-resistant high-alloy special stainless steels.

At the bottom of the table is the age-hardenable nickel–chromium–iron–molybdenum (–copper) alloy group that is of great importance in the special application of oil and gas extraction.

Although the list of the principal nickel alloy groups for aqueous corrosive applications presented in **Table 1** seems to be quite large, it shows a selection of the most important alloys only. The great number of nickel alloys for aqueous corrosive applications that are available today is the result of a phenomenal recent growth in the development of new nickel alloys, with special emphasis on the high-performance nickel–chromium–molybdenum alloy group. This development of new alloys has become possible by the introduction of new metallurgical techniques like argon–oxygen–decarburization (AOD) and vacuum–oxygen–decarburization (VOD) in the 1960s. These new metallurgical techniques allow easy decarburization of large volumes of molten alloys down to very low carbon contents as, for instance, 0.005 mass%. **Table 2** gives a brief listing of developments of some nickel alloys during the pre-1950s and since the 1950s.<sup>1</sup> As is evident from this listing, today's corrosion and material engineers

have a much wider selection of alloys to meet their specific needs than had been the case prior to the 1950s when the alloy choices available for combating aqueous corrosion were very limited. This historical development has to be kept in mind when reading older literature on corrosion-resistant materials. New alloys and refinements of old ones are constantly under way.

### 3.05.3 Nickel and Nickel Alloy Groups for Aqueous Corrosive Applications

#### 3.05.3.1 Nickel

As Friend<sup>2</sup> points out, the standard reduction potential of nickel that is shown in the electrochemical series of metals is nobler than that of iron and less noble than that of copper. Owing to nickel's marked hydrogen overpotential, hydrogen is not so easily liberated from the usual nonoxidizing acids, and the presence of oxygen, for example, from dissolved air is generally necessary here in order to allow corrosion to proceed. The general rule is that oxidizing conditions promote the corrosion of nickel in chemical solutions, whereas reducing conditions retard it. However, nickel has the ability to protect itself against certain forms of corrosive attack by forming a passive layer of oxide or hydrated oxide, and in practice often exhibits a more noble behavior than does copper. Therefore, corrosion is not always accelerated by oxidizing conditions. A certain amount of pitting may occur if the passive layer is locally destroyed, for example, in hot chloride solutions. The results of the studies of the mechanism of passivation of nickel have been reviewed extensively by Friend.<sup>2</sup>

If the temperature is not excessively high, nickel has a useful measure of resistance to corrosive attack by dilute nonaerated solutions of most of the nonoxidizing mineral acids, for example, sulfuric, hydrochloric, and phosphoric acid. This also applies to the nonoxidizing salts of such acids, which can hydrolyze with the formation of dilute solutions of these

**Table 2**      Historical development and introduction to the market of selected nickel alloys

Alloy	Period					
	Pre-1950s	1950s	1960s	1970s	1980s	1990s
Ni, Ni–Cu, Ni–Cr	200, 400, 600					
Ni–Mo	B			B-2		B-2 'controlled composition'
Ni–Fe–Cr–Mo–Cu		825	20, G	G-3	G-30	31, 33
Ni–Cr–Mo	C		C-276, 625	C-4	22	59, 686, 2000, MAT 21

acids. Nickel may corrode rapidly in oxidizing acids, for example, nitric acid, or in other mineral acids containing significant amounts of oxidants.

Nickel has a useful measure of corrosion resistance to most nonaerated organic acids and other organic compounds. This enables it to be used in the plastics industry. When being used in the food industry, nickel itself might exhibit a sufficient level of corrosion resistance in the medium under consideration, nevertheless attention has to be paid to the amount of nickel ions that might migrate into the food, and for this reason, nickel-plated food contact materials should not be used.<sup>3</sup>

Nickel is very resistant to corrosion by most kinds of natural and highly purified water. However, if water intended for human consumption is considered, the size of the surface of the nickel-plated parts being exposed to the water should be limited and a sufficient amount of flow maintained as well, in order to avoid an excessive uptake of nickel by the drinking water, and in this way, meet the requirements of the European Council Directive 98/83/EC on the quality of drinking water.<sup>4</sup>

Nickel is also resistant to fast-flowing seawater. Under stationary conditions, however, it is susceptible to substantial growth of organisms, with the result that severe local attack may occur under this and other deposits.

Nickel is outstandingly resistant to alkalis such as sodium and potassium hydroxide, even at high concentrations and temperatures, with the exception of more highly concentrated ammonium hydroxide solutions, and to nonoxidizing alkaline and neutral salts. This property is the reason for nickel's use in chemical process equipment manufacturing for the production and processing of caustic soda and caustic potash. **Figure 1** shows an isocorrosion diagram of nickel in caustic soda solution originally established more than 30 years ago<sup>5</sup> and redrawn more recently,<sup>6</sup> due to its unique importance for the industrial application of metallic nickel. Obviously, in practice, this diagram can only be used as an initial guide, because admixtures and impurities that may be present in the caustic soda influence the metal's corrosion behavior.

More detailed information on nickel's corrosion behavior is provided by Friend.<sup>2</sup> In traditional parlance, unalloyed nickel in wet-corrosion applications is referred to as 'pure nickel.' The most popular grades for wet-corrosion service are the standard grade alloy 200 (EN 2.4066/UNS N02200) and the low-carbon grade alloy 201 (EN 2.4068/UNS N02201) shown in **Table 1**. The low-carbon grade must be used at temperatures in excess of 315 °C (600 °F) in order to

**Figure 1** Corrosion resistance of unalloyed nickel in sodium hydroxide, related to concentration and temperature. Reproduced from Heubner, U. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Ed.; Expert Verlag: Renningen, 2003; Chapter 2, pp 47–93.

avoid loss of ductility because of the precipitation of graphite at the grain boundaries within the metal's microstructure.<sup>2</sup> In addition, unalloyed nickel when used in electroplated form, mainly on steel and brass, may be exposed to wet-corrosive attack too.

### 3.05.3.2 Nickel–Copper Alloys

Copper is reasonably corrosion-resistant in dilute, nonoxidizing, nonaerated solutions of mineral acids such as sulfuric, hydrochloric, phosphoric, or hydrofluoric acid, and also of most organic acids, for example, acetic and formic acid, even at quite high temperatures. It is attacked by hot concentrated solutions of these acids. When nickel and nickel alloys are alloyed with copper, their resistance to these nonoxidizing acid solutions is generally improved. In particular, copper is often added to increase the corrosion resistance of nickel alloys and high-alloy special stainless steels in sulfuric acid.

Nickel–copper alloys containing, for instance, 27–34 mass% copper may have a useful measure of corrosion resistance in nonaerated sulfuric acid at concentrations of up to 80% at room temperature, 60% at 70 °C, and 20% at boiling temperature (Craig and Anderson<sup>7</sup> indicate data that are at variance with this).

Nickel–copper alloys are reasonably resistant to dilute hydrochloric acid solutions, provided that, like

the aforementioned sulfuric acid solutions, they are kept free of air. These alloys can then be used at hydrochloric acid concentrations of up to ~15% at room temperature and ~5% at ~70 °C. Therefore, they can be used for handling nonoxidizing chlorides, which form hydrochloric acid in low concentrations by hydrolysis in the presence of water.

Nickel–copper alloys are one of the few types of metallic materials that exhibit good corrosion resistance in nonaerated hydrofluoric acid of all concentrations. In aerated solutions, on the other hand, severe metal dissolution and stress-corrosion cracking may occur. The corrosion rates are shown in detail in the isocorrosion diagram for nonaerated and aerated solutions.

Nickel–copper alloys are resistant to most kinds of water; their resistance to seawater with a high flow-velocity is particularly relevant for their use in actual service. They can therefore be used for, among other things, heat exchanger tubes and for shielding in seawater spray and tidal zones. The age-hardenable variant is used in places where not only resistance to seawater but also high strength are important, for example, for ship propeller shafts, valve seats, studs, bolts, and pump components. Under stationary conditions, incrustation by marine organisms can occur, causing concentration cells to form, which result in pitting. This, however, tends to slow down with time and even, in tropical waters, seldom exceeds penetration depths of ~0.75 mm (30 mils) after a few years.

Thanks to their high nickel content, nickel–copper alloys are resistant to most alkalis (except ammonium hydroxide) and most nonoxidizing alkaline and neutral salts. They have good resistance in caustic soda and caustic potash, similar to that of unalloyed nickel. Rates of corrosion of less than 0.05 mm year<sup>-1</sup> were found up to a concentration of 75% NaOH and a temperature of 130 °C. When 75% NaOH is evaporated to anhydrous NaOH, the corrosion rates are higher than with unalloyed nickel, and in molten NaOH, stress-corrosion cracking was observed in equipment items subjected to high mechanical stress. Under such conditions, therefore, the components must undergo stress-relief annealing.

Neutral and alkaline salt solutions such as chlorides, carbonates, sulfates, nitrates, and acetates have only a minimal corrosive effect on nickel–copper alloys, even at high concentrations and temperatures up to the boiling point; consequently, corrosion rates are generally less than 0.025 mm year<sup>-1</sup>. Nickel–copper alloys are, therefore, used in plants in which salts are crystallized from saturated brines.

Nickel–copper alloys are not resistant to highly oxidizing solutions such as nitric and chromic acid, moist chlorine, and hypochlorites.

The most important nickel–copper alloys for engineering purposes are alloy 400 (EN 2.4360/UNS N04400) and the age-hardenable variant alloy K-500 (EN 2.4375/UNS N05500) as mentioned in [Table 1](#).

Related, in the broader sense, to the nickel–copper alloys are the copper–nickel alloys, which are dealt with in [Chapter 3.07, Corrosion of Copper and its Alloys](#).

### 3.05.3.3 Nickel–Molybdenum Alloys

Molybdenum exhibits a very good corrosion resistance to nonoxidizing solutions of hydrochloric, phosphoric, and hydrofluoric acid at most concentrations and temperatures and to boiling sulfuric acid up to a concentration of ~60%. The alloying of nickel and nickel alloys with molybdenum improves their corrosion resistance in these media approximately in proportion to the percentage of added molybdenum. Nickel–molybdenum alloys, which typically contain 26–30 mass% molybdenum, are among the few metallic materials that are resistant to nonaerated hydrochloric acid at all concentrations and temperatures.<sup>6</sup> The prerequisite is the absence of oxidizing additions such as dissolved oxygen and heavy metal ions. Otherwise, the corrosion rates can increase significantly, as the isocorrosion diagrams shown by Craig and Anderson<sup>7</sup> for the alloy type B-2 make clear by way of example.

In nickel–molybdenum alloys, the practicable molybdenum content is subject to an upper limit owing to the constitutional situation.<sup>8–10</sup> As shown in [Table 1](#), the commercial alloy B-2 typically contains 28 mass% molybdenum. As [Figure 2](#) makes clear,<sup>6,11</sup> at this molybdenum content, a minimal rate of corrosion, which depends only to a slight extent on variations in the molybdenum content, can be anticipated in tests in boiling 10% hydrochloric acid as a test method, which is widely used in such circumstances.

Up to the mid-1990s, problems were frequently encountered when working and using the technologically established alloy B-2 (EN 2.4617/UNS N10665) because of fractures during working and stress-corrosion cracking while in service. The cause of both the fall in ductility and the stress-corrosion cracking is considered to be the formation of the ordered Ni<sub>4</sub>Mo phase,<sup>9,10</sup> a phenomenon that is accelerated by cold deformation.<sup>12</sup> A thorough

**Figure 2** Influence of the molybdenum content on the corrosion resistance of nickel-molybdenum alloys in boiling 10% hydrochloric acid.<sup>6,11</sup>

**Figure 3** Time-temperature-notch impact energy diagrams for the alloy NiMo28 – alloy B-2 (EN 2.4617/UNS N10665), established using three melts with different iron and chromium contents.<sup>6,8</sup>

analysis showed that the risk of such damage can be greatly reduced if the iron and chromium contents of this type of alloy are set close to the upper limit of what is acceptable according to the specification.<sup>10</sup>

**Figure 3** reveals by way of example how with this material the decrease in ductility during a working-related input of heat in the medium temperature range is delayed with increasing iron and chromium contents. It is due to these findings that a new alloy B-2 ‘controlled composition’ with Fe at 1.7 and Cr at 0.7 mass% as typical values, as shown in **Table 1**, had been introduced to the market in the 1990s (cf. **Table 2**). Nevertheless, solution annealing

of cold-formed parts, for example, heads, may be necessary when deformation is greater than 7% outer fiber elongation of cold work in order to avoid susceptibility to cracking at welds and heat affected zones during subsequent fabrication or later service.

The isocorrosion diagram plotted for alloy B-2 (EN 2.4617/UNS N10665) in nonaerated sulfuric acid shows interesting areas of resistance, for example, at concentrations between 60% and 80% and at temperatures above 120 °C. This too is subject to the prerequisite that clearly reducing conditions must be present; oxygen inputs due to aeration, heavy metal ions, and other oxidants accelerate corrosion.<sup>6,7</sup>

The corrosion resistance of alloy B-2 (EN 2.4617/UNS N10665) in organic acids, especially acetic acid, is tied to similar conditions.<sup>2</sup>

Thanks to its extremely low carbon and silicon contents, the NiMo28 alloy B-2 (EN 2.4617/UNS N10665) has good resistance to knife-line corrosion and selective corrosion in the heat-affected zone (HAZ) and can therefore usually be used in the welded state without further heat treatment.

### 3.05.3.4 Nickel–Chromium Alloys

Nickel and nickel alloys are alloyed with chromium to improve their resistance to strongly oxidizing media. Substances of this kind include nitric acid, chromic acid, and some acidic solutions containing oxidizing salts, with the exception of chlorides. In this case, corrosion resistance increases approximately in proportion to the chromium content, provided that it is more than 10 wt%. In the case of aerated acidic solutions, especially at elevated temperatures, chromium contents of more than 18% are preferable.<sup>2</sup>

**Figure 4** serves as a typical example of the effect of chromium on the reduction of the corrosion rate in strongly oxidizing solutions, referring as much to iron–chromium–nickel alloys as to nickel–chromium–iron alloys as shown by the example of alloy 690 (cf. **Table 1**). The difference between the older data and the newer data reflects the introduction of the melting technologies AOD and VOD, which occurred in the 1960s and resulted in cleaner alloys. Internal cleanness of the metallic grain structure is an often overlooked prerequisite for an enduring resistance to corrosive attack in the passive/transpassive and in the transpassive area, as may happen in strongly oxidizing solutions such as boiling azeotropic nitric acid as in **Figure 4**.

Since nickel–chromium alloys require the presence of further alloying elements in order for them

**Figure 4** Corrosion of iron–chromium–nickel and nickel–chromium–iron alloys in boiling azeotropic nitric acid.<sup>13,14</sup>

to be universally suitable for wet-corrosion service, they are few in number and their use tends to be limited to special cases. In current engineering practice, there are only two that are commonly used: alloy 600 L (EN 24817/UNS N 06600) and alloy 690 (EN 24642/UNS N 06690). As shown in [Table 1](#), these alloys also have a nominal iron content of 9 mass%. This means that, strictly speaking, they are nickel–chromium–iron alloys. Owing to their high nickel content, both can be considered for corrosive attack by hot alkaline solutions if they contain oxidants; examples are chlorates from diaphragm cells or sulfur compounds. These types of alloy are also used for steam generators in nuclear power stations. Owing to its high chromium content, alloy 690 has also been considered for corrosive attack by strongly oxidizing media. Nowadays, however, as is evident from [Figure 4](#), the more recently developed alloy 33 (EN 1.4591/UNS R20033) is probably a better alternative.<sup>13,14</sup>

### 3.05.3.5 Nickel–Chromium–Molybdenum Alloys

#### 3.05.3.5.1 General

As is to be expected, nickel–chromium–molybdenum alloys combine the good resistance to corrosion of nickel–molybdenum alloys under reducing conditions

with the good resistance to corrosion exhibited by nickel–chromium alloys under oxidizing conditions. The most important for engineering purposes are the so-called C-type alloys, the first of which was introduced as long ago as the 1930s. This was a nickel alloy with typically (figures in mass%) 16% chromium and 16% molybdenum, which also contained 4% tungsten and 6% iron together with 0.7% silicon and 0.05% carbon; this alloy is no longer in common use.<sup>15</sup> With the discovery that to reduce precipitation-readiness, it is important to reduce both the carbon and the silicon content of such materials to very low levels, it was developed into the alloy C-276 (EN 24819/UNS N10276), which is in use today, as shown in [Table 1](#). Since the 1960s, this has also been possible on a large scale without major problems, thanks to the new AOD and VOD production processes, which were introduced from that date onwards (cf. [Section 3.05.3.4](#)). Low silicon contents of typically 0.04 mass% and very low carbon contents of typically 0.005 mass% are nowadays characteristic of all the commonly used C-type nickel–chromium–molybdenum alloys,<sup>15</sup> which also include the alloys C-4 (EN 24610/UNS N06455), 22 (EN 24602/UNS N06022), and 59 (EN 24605/UNS N06059) in [Table 1](#).

#### 3.05.3.5.2 Alloy C-276

Alloy C-276 (EN 24819/UNS N10276) has its main areas of use for prevailing corrosive attack by reducing acids such as sulfuric acid, phosphoric acid, hydrochloric acid, and organic acids. Its isocorrosion diagram in technical grade sulfuric acid is reproduced in [Figure 5](#).

Owing to its good corrosion resistance in predominantly reducing media, even in the presence of halogens, it has succeeded in conquering a wide range of applications in the chemical industry; today, however, these are increasingly being taken over by the subsequently developed alloy 59 (see later text), which can be used on a more universal scale. This applies, for example, to plate-type heat exchangers in sulfuric acid production, which operate at reduced temperatures. Alloy C-276 is also used in applications where its resistance to hydrochloric acid solutions comes to the fore, for example, in the production of vinyl chloride monomer (VCM), methylene di-*para*-phenylene isocyanate (MDI), and toluene diisocyanate (TDI). Moreover, this type of alloy has good resistance to acetic acid at all concentrations and temperatures,<sup>7</sup> and is used for handling oxidizing acetic acid solutions and in places where acetic acid occurs in combination with inorganic acids and salts,

**Figure 5** Isocorrosion diagram of alloy C-276 (EN 2.4819/UNS N10267) in slightly aerated technical grade sulfuric acid, determined by immersion tests over at least 120 h. Reproduced from Kirchheiner, R.; Wahl, V. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Ed.; Expert Verlag: Renningen, 2003; Chapter 8, pp 255–294.

which restrict the use of stainless steels.<sup>7</sup> Alloy C-276 has proved to be resistant to chloride-induced stress-corrosion cracking under very aggressive sour-gas conditions, even in the presence of elemental sulfur, but is susceptible to hydrogen-induced stress-corrosion cracking in such media below a temperature of 100 °C.<sup>16</sup> The material's capabilities are also well proven in environmental technology where it has a broad area of use in flue gas desulfurization (FGD).<sup>17</sup> Other important industries in which this type of alloy has become established together with its C-4 variant, which is described in the following section, are listed by Agarwal *et al.*<sup>15</sup> Some details of this material and its corrosion behavior are discussed in the following section in comparison with the other C-alloys.

### 3.05.3.5.3 Alloy C-4

Alloy C-4 (EN 2.4610/UNS N06455) is a variant of alloy C-276, which is in common use in the European chemical industry in particular. As shown in [Table 1](#), it differs from the latter material in the absence of tungsten as an alloying element and greatly reduced iron content. Consequently, the alloy is less resistant in predominantly reducing media, but is much less prone to precipitation and very much easier to work, with the result that, on its commercial launch in the 1970s, it rapidly gained acceptance in the chemical industry. The important chemical industry applications include fertilizer and pesticide production processes and the production of pharmaceutical

intermediates, acetic acid, and inorganic chemicals. In the version without the addition of titanium that is supplied by ThyssenKrupp VDM GmbH, it is free from titanium nitrides. This enables a uniformly smooth surface, which remains smooth, to be obtained in electropolishing and comparable conditions, for example, current feeding rollers in electrolytic plating.

### 3.05.3.5.4 Alloy 22

With alloy 22 (EN 2.4602/UNS 06022), a nickel–chromium–molybdenum alloy typically containing 22 mass% chromium and 13 mass% molybdenum together with 3 mass% tungsten and 3 mass% iron, which was brought into the market in the mid 1980s,<sup>15</sup> a material became available which, owing to the increased chromium content, has better corrosion resistance than do alloy C-276 and alloy C-4 in oxidizing media. However, owing to the reduced molybdenum content, the effect of which can only be partly compensated for by the tungsten addition, it is inferior to alloy C-276 in strongly reducing media and in conditions of extreme crevice corrosion attack.<sup>15</sup> The subsequently developed alloy 59 also exhibits, according to Heubner<sup>6</sup> and the following remarks, a more favorable behavior than does alloy 22 in many respects.

### 3.05.3.5.5 Alloy 59

Alloy 59 (EN 2.4605/UNS N06059), with its composition of 23 mass% chromium and 16 mass% molybdenum, is a considerable advance on alloy 22. This material,<sup>15</sup> which was introduced into engineering practice in the early 1990s, is not only far superior to the other nickel–chromium–molybdenum alloys listed in [Table 1](#) in handling reducing acids, even if contaminated, their main area of application, but has also been successfully qualified for further duties such as the handling of highly corrosive salt solutions resulting from waste water treatment in FGD<sup>18</sup> and control of critical crevice corrosion problems in seawater,<sup>15</sup> including those occurring in plate-type heat exchangers cooled with chlorinated seawater.<sup>19</sup>

Its isocorrosion diagram in aerated technical grade sulfuric acid, plotted using results from immersion tests, is depicted in [Figure 6](#). It shows a broad range of resistance, which, in these test series, falls only slightly below 100 °C up to a concentration of ~60% H<sub>2</sub>SO<sub>4</sub>. The corrosion behavior of alloy 59 in sulfuric acid is not influenced greatly by the amounts of oxidants present in the acid and is also less impaired by the presence of chlorides than is the

corrosion behavior of alloys that are more difficult to passivate.<sup>20</sup>

**Figure 7** depicts the isocorrosion diagram for alloy 59 in hydrochloric acid, also plotted using results from immersion tests. It shows that this material is resistant at all HCl concentrations up to at least 40 °C. This, however, means among other things, that it is corrosion resistant in many organic process media in which hydrochloric acid is formed, which with other materials would lead to corrosion damage.

**Figure 6** Isocorrosion diagram of alloy 59 (EN 2.4605/UNS N06059) in slightly aerated technical grade sulfuric acid, determined by immersion tests over at least 120 h. Reproduced from Kirchheiner, R.; Wahl, V. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Ed.; Expert Verlag: Renningen, 2003; Chapter 8, pp 255–294.

**Figure 7** Isocorrosion diagram for alloy 59 (EN 2.4605/UNS N06059) in hydrochloric acid, determined by static immersion tests.<sup>14,21</sup>

Alloy 59 should also be considered as a very attractive material for handling aerated hydrofluoric acid.<sup>15</sup> Finally, as shown in **Figure 8**, the results of testing in an oxidizing sulfuric acid solution in accordance with ASTM G-28 method A are also of interest. Even though they are not directly relevant to practical use, they illustrate, by way of example, the influence of the chromium to molybdenum plus tungsten ratio on the corrosion behavior of nickel–chromium–molybdenum alloys under oxidizing conditions.<sup>6,21</sup>

The ‘Green Death’ solution (11.5% H<sub>2</sub>SO<sub>4</sub> + 1.2% HCl + 1% FeCl<sub>3</sub> + 1% CuCl<sub>2</sub>), which is widely used for testing the pitting resistance of nickel–chromium–molybdenum alloys and which simulates acidic condensates of the kind that can occur in the flue gas ducts of coal-fired power stations, shows a critical pitting temperature (CPT) of >120 °C for alloy 59, compared with 120 °C for alloy 22, 115–120 °C for alloy C-276, and 100 °C for alloy C-4.<sup>22</sup> The Green Death solution decomposes at temperatures above 120 °C, which means that there is no point in measuring temperatures in excess of 120 °C. However, a further differentiation of the pitting behavior of very high-alloyed materials is enabled by the CaCl<sub>2</sub> test,<sup>23</sup> a potentiostatic holding test at

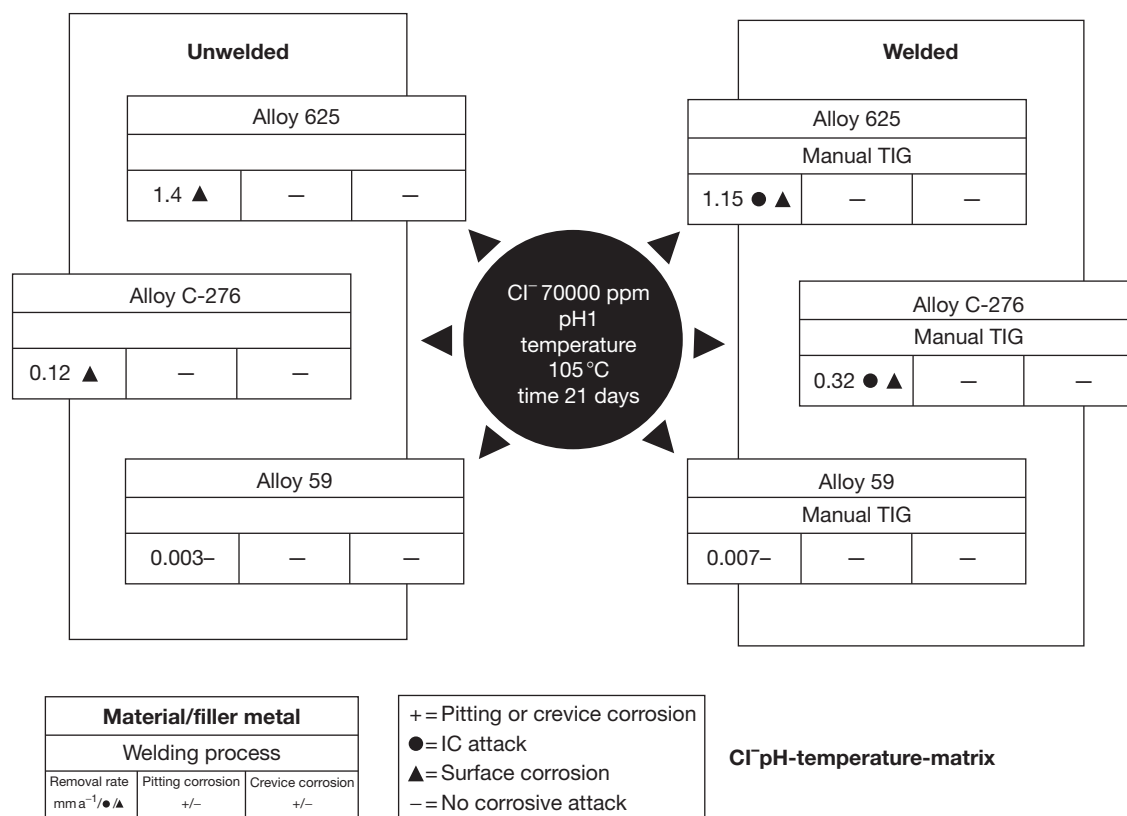

**Figure 8** Corrosion loss of nickel–chromium–molybdenum alloys in boiling 50% H<sub>2</sub>SO<sub>4</sub> with 42 g l<sup>−1</sup> Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>·9H<sub>2</sub>O in accordance with ASTM G-28 A as a function of their ratio of chromium to molybdenum plus tungsten.<sup>6,21</sup>

0.2  $V_{\text{SCE}}$  in a 4.5 mol  $\text{l}^{-1}$  (500 g  $\text{l}^{-1}$ )  $\text{CaCl}_2$  solution boiling at 115 °C, which for alloy 59 gives a CPT of 100 °C, compared with 83 °C for alloy C-276. A realistic pitting test for FGD is the testing of unwelded and welded specimens at the chloride–pH–temperature matrix intersection  $\text{Cl}^-$  7%/pH 1/ $T$  105 °C, which is described with results in Figure 9 and which likewise shows that the performance of alloy 59 is superior to that of other nickel–chromium–molybdenum alloys.<sup>17</sup>

The time–temperature–sensitization diagram, which is discussed in the following section, shows that alloy 59 is supremely resistant to thermal influences. The harmonious relationship of outstanding corrosion behavior accompanied by good workability is the special distinguishing feature of alloy 59. This alloy is therefore used in many areas of chemical process technology and other process industries,<sup>24</sup> in marine technology,<sup>25</sup> as well as in environmental engineering on a very large scale.<sup>17,26</sup>

### 3.05.3.5.6 Additional C-alloys and thermal stability as a criterion for alloy selection

The additional alloy C variants, which have been brought onto the market since the introduction of alloy 59 are alloy 2000 (EN 2.4675/UNS N06200), which typically contains 23 mass% chromium and 16 mass% molybdenum plus 1.6 mass% copper and 1.5 mass% iron, alloy MAT 21 (UNS N06210) which, as shown in Table 1, typically contains both 19 mass% chromium and molybdenum and 1.8 mass% tantalum in addition, and alloy 686 (EN 2.4606/UNS N06686), which, as shown in Table 1, typically contains 21 mass% chromium, 16 mass% molybdenum and also 3.8 mass% tungsten and 1.5 mass% iron. With respect to alloy MAT 21, insufficient data are available to discuss its localized corrosion behavior and thermal stability. Alloy 2000 clearly attempts to take advantage of the well known influence of copper on the corrosion resistance of

**Figure 9** Comparison of the corrosion behavior of NiCrMo materials in a diluted sulfuric acid-containing solution with 7% chloride addition; base materials unwelded and base materials welded with matching filler metal using the tungsten inert gas (TIG) process; corrosion rate given in  $\text{mm year}^{-1}$ , see legend for local corrosion assessment. Reproduced from Kirchheiner, R.; Wahl, V. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Ed.; Expert Verlag: Renningen, 2003; Chapter 8, pp 255–294.

nickel alloys and high-alloyed special stainless steels in sulfuric acid.<sup>27</sup> In case of alloy 686, it is evident from the composition that the intention was to shift the best available corrosion resistance more toward reducing conditions. Both alloys achieve their special corrosion behavior at the expense of a thermal stability that is markedly inferior to that of alloy 59, as shown in **Table 3** by reference to the corrosive attack after sensitizing annealing treatment.<sup>15</sup>

The thermal stability of nickel–chromium–molybdenum alloys is an important criterion for their use, for example, in welding of thick-walled vessels where multipass welding is necessary, or in hot deformation of thick cross-sections. A fuller idea of the outstanding thermal stability of alloy 59 compared with alloy 686 and alloy 2000 with reference to the corrosive attack after sensitizing annealing treatment for periods ranging from 0.3 to 10 h at temperatures between 650 and 1000 °C is given<sup>6</sup> in **Figure 10**.

A further comparison is given by the time–temperature–sensitization diagrams<sup>26</sup> as shown in **Figure 11**. It is evident that alloy C-276 is very susceptible to intercrystalline corrosion (IC) under such criteria. In fact, this alloy is neither intended nor suitable for use under the kind of oxidizing conditions that are specified by the test in accordance with ASTM G-28 A. By contrast, alloy 59 performs significantly better under these oxidizing conditions, also in comparison with the other two nickel–chromium–molybdenum alloys C-4 and 22. Sensitization in the sense of an intercrystalline 50 µm depth of penetration IC criterion only begins after 2 h at the earliest. This is an adequate time in practice for avoiding IC after hot-forming, heat treatment, and welding even of thick dimensions.

### 3.05.3.5.7 Alloy 625

Alloy 625 (EN 2.4856/UNS N06625) is listed in **Table 1** as the leanest of the nickel–chromium–molybdenum alloy group. As is evident, it differs from the previously described C-type nickel–chromium–molybdenum alloys in that it is stabilized with niobium. Also, it has the lowest molybdenum content of 9 mass%, and hence the lowest pitting resistance of this group of alloys, but owing to its niobium content, the effect of which is similar to that of molybdenum, it gives the appearance, in terms of its corrosion behavior, of having a somewhat higher alloying content of molybdenum. This alloy was originally developed for high temperature applications, but is now widely used in wet-corrosion service. The isocorrosion diagram for this type of material in sulfuric acid is shown in Craig and Anderson.<sup>7</sup> Its high mechanical strength and good resistance to acids<sup>7</sup> enable the fabrication of thin-walled components with good heat transmission. As can be inferred from the chromium-to-molybdenum ratio and is confirmed by **Figure 8**, its preferred area of use is more on the oxidizing side. It is used in the processing of phosphate ores with fairly high impurity content because of its corrosion and erosion resistance to the phosphate slurries in the digestion reactor and in the evaporation equipment of the final stage.<sup>7</sup> However, in the processing of phosphate ores, alloy 625 is increasingly replaced by alloy 31 (EN 1.4562/UNS N08031), which, due to its higher chromium content, performs much better, and is more cost-effective in addition (cf. **Section 3.05.5.4**). Alloy 31 has increasingly taken the place of alloy 625 in flue gas cleaning too, where alloy 625 was typically used under less aggressive conditions not requiring the use of alloy 59. Also, worthy of mention is the use of alloy 625 for borehole equipment and flow lines under sour-gas conditions.

**Table 3** Thermal stability, stated as corrosion loss in millimeter per year after a sensitizing heat treatment for 1, 3, and 5 h at 87 °C (1600 °F) in tests in accordance with ASTM G-28 A and with ASTM G-28 B, according to data from Agarwal and Herda<sup>15</sup>

Test	Sensitization (h)	Alloy				
		C-276	22	686	C-2000	59
ASTM G-28 A	1	>12.5 <sup>a</sup>	>12.5 <sup>a</sup>	22.2 <sup>a</sup>	3.0 <sup>a</sup>	1.0 <sup>b</sup>
	3	>12.5 <sup>a</sup>	>12.5 <sup>a</sup>	>25.4 <sup>a</sup>	4.5 <sup>a</sup>	1.3 <sup>b</sup>
	5	>12.5 <sup>a</sup>	>12.5 <sup>a</sup>	>25.4 <sup>a</sup>	5.3 <sup>a</sup>	–
ASTM G-28 B	1	>12.5 <sup>a</sup>	8.6 <sup>a</sup>	0.4 <sup>a</sup>	>12.5 <sup>a</sup>	0.1 <sup>b</sup>
	3	>12.5 <sup>a</sup>	8.0 <sup>a</sup>	2.2 <sup>a</sup>	>12.5 <sup>a</sup>	0.1 <sup>b</sup>
	5	>12.5 <sup>a</sup>	>12.5 <sup>a</sup>	>12.5 <sup>a</sup>	>12.5 <sup>a</sup>	0.4 <sup>b</sup>

<sup>a</sup>The alloys C-276, 22, C-2000, and 686 exhibit severe pitting and intercrystalline corrosion with grains dropping out.

<sup>b</sup>Alloy 59 exhibits no pitting.

**Figure 10** Thermal stability of alloy 59 (EN 2.4605/UNS N06059) compared with alloys 686 (EN 2.4606/UNS N06686) and 2000 (EN 2.4675/UNS N06200), measured as corrosive attack in tests in accordance with ASTM G-28 A after sensitizing heat treatments for 0.3–10 h at between 650 and 1000 °C. ### 3.05.3.6 Nickel–Chromium–Iron–Molybdenum–Copper Alloys

#### 3.05.3.6.1 General

Nickel–chromium–iron–molybdenum–copper alloys occupy a position between the nickel–chromium–molybdenum alloys and the high-alloy steels. Consequently, they are more limited in their application than the nickel–chromium–molybdenum alloys, but are significantly more corrosion resistant than the popular stainless steels in a large number of industrial

**Figure 11** Time–temperature–sensitization diagrams of various nickel–chromium–molybdenum alloys,<sup>26</sup> established in tests in accordance with ASTM G-28 A.

media. One of their characteristics is that, due to their still relatively high nickel content, they have excellent resistance to stress-corrosion cracking in aqueous and acidic media containing chloride ions. With the exception of alloy 33, these alloys are particularly intended for use in the reducing acids sulfuric acid and phosphoric acid. The alloys in question with their chromium, molybdenum, and tungsten contents in ascending order (cf. Table 1) are alloy 20 (EN 2.4660/UNS N08020), alloy 825 (EN 2.4858/UNS N08825), alloy G-3 (EN 2.4619/UNS N06985), alloy 31 (EN 1.4562/UNS N08031), alloy 33 (EN 1.4591/UNS R20033), and alloy G-30 (EN 2.4603/UNS N06030). Their resistance in sulfuric acid is significantly improved by the alloying addition of copper.<sup>27</sup>

#### 3.05.3.6.2 Traditional materials: Alloys 20, 825, G-3, and G-30

The alloys 20, 825, G-3, and G-30 can be considered traditional materials in that they are making use of titanium or niobium as stabilizing additions in combination with rather high nickel contents. Alloy 825's high stabilization with titanium marks it out as a veteran of material technology, which was developed before the 1960s (cf. Table 2). According to the isocorrosion diagram reproduced in Craig and Anderson,<sup>7</sup> it can be considered resistant to sulfuric acid of all concentrations up to a temperature of at least 50 °C with a corrosion rate of <0.13 mm year<sup>-1</sup>. Its corrosion resistance is further improved by the presence of nitric acid and oxidizing salts.<sup>7</sup> If the requirements are not too stringent, this very traditional yet versatile material can also be used for handling nitric acid and caustic soda solutions.<sup>7</sup> Alloy 20 can be regarded as a variant of alloy 825 with reduced nickel, chromium, and molybdenum

contents but an enhanced copper content. According to the comparative isocorrosion diagram,<sup>7</sup> its corrosion resistance in sulfuric acid is predominantly somewhat lower than that of alloy 825. Alloy 20 is a material of construction for sulfuric and phosphoric acid heat exchangers and pipes, which is in common and widespread use in the United States in particular. Alloy 825, on the other hand, is also used in the offshore sector as a preferred material for heat exchangers, product piping, and conveying pipes. Both the alloys are resistant to hydrofluoric acid of all concentrations at room temperature and at concentrations up to 10% HF at 70 °C.<sup>7</sup>

In view of the pitting resistance equivalent (PRE) relationship, which plays a dominant role here, both alloy 825 and alloy 20 can be expected to exhibit comparatively low resistance to pitting and crevice corrosion in chloride-containing media, including seawater. However, alloy 825 has a remarkably high resistance to chloride-induced stress-corrosion cracking with preceding pitting corrosion in aggressive sour-gas media.<sup>28</sup> Therefore, for this kind of attack, a parameter  $\Sigma = \text{Ni} + 2\text{Mo} + 0.5\text{Cr}$  (for  $\text{Mo} \geq 2.5$ ) calculated as mass% has been tentatively proposed by Rhodes<sup>16</sup> as a measure of alloy resistance in place of the commonly used PRE written for instance<sup>16</sup> as  $\text{PRE} = \text{Cr} + 3.3\text{Mo} + 30\text{N}$ . However, as the PRE shows very clearly, in the case of alloy 825, the fixing of all the available nitrogen by the titanium is not an advantage, and in the case of alloy 20, the high copper content is more likely to have a detrimental effect on its crevice corrosion resistance.<sup>6</sup> This weakness is counteracted by the higher molybdenum content of the variant alloy G-3, which is increased to 7 mass % nominal as shown in **Table 1**. Besides the handling of sulfuric and phosphoric acid, this type of alloy can also be used in acetic acid production<sup>7</sup> and for tubular products in oil and gas extraction. However, there are applications where more advanced materials such as alloy 31 (EN 1.4562/UNS N08031) have been substituted successfully for the traditional alloy G-3, and this change is expected to continue.

Alloy G-30 is a modification of alloy G-3, with increased chromium content and lower molybdenum content. Alloy G-30 has excellent corrosion resistance in commercial phosphoric acids as well as in many complex and mixed acid environments of nitric/hydrochloric and nitric/hydrofluoric acids. The alloy also shows good corrosion resistance to sulfuric acid. Typical applications of alloy G-30 are

in phosphoric acid service, mixed acid service, nuclear fuel reprocessing, components in pickling operations, agrichemicals manufacture, and mining industries.<sup>1</sup>

### 3.05.3.6.3 Advanced materials: Alloys 31 and 33

As shown in **Table 1** the alloys 31 and 33 are a new type of nickel–chromium–iron–molybdenum–copper materials characterized by lower content of nickel in order to save on the cost of raw materials, and instead of stabilizing alloying additions they contain appreciable amounts of nitrogen, which provides increased resistance to pitting corrosion and increased strength. It is for these reasons that they deserve a more detailed presentation.

According to **Table 1**, alloy 31 (EN 1.4562/UNS N08031) with the sum of its alloying elements chromium, molybdenum, and copper is higher than alloy G-3, whereas it is remarkably lower in nickel. In view that the amount of the alloying elements chromium, molybdenum, and copper, to a large extent, determines the corrosion behavior, alloy 31 can be taken as an excellent example for what can be done more with respect to corrosion resistance with less cost of raw materials. The isocorrosion diagram established by means of immersion tests in aerated technical grade sulfuric acid is reproduced in **Figure 12**. However, the presence of oxidants is important for the corrosion resistance of alloy 31 in sulfuric acid at concentrations above ~10%. Therefore, when testing in analytical grade sulfuric acid instead of aerated technical grade sulfuric acid, the 0.1 mm year<sup>−1</sup> isocorrosion line will be shifted to lower temperatures as shown in **Figure 13**, which results from detailed studies.<sup>20</sup> The presence of chlorides will shift the 0.1 mm year<sup>−1</sup> isocorrosion line of alloy 31 to lower temperatures too.<sup>20</sup>

In the production of phosphoric acid, the presence of chlorides, fluorides, oxidizing metal ions, and possibly further corrosion-accelerating impurities such as an influence of erosion or deposit formation should be anticipated depending on the composition of the phosphate ores. This means that for the concentration stage (>50% H<sub>3</sub>PO<sub>4</sub>), only special stainless steels or nickel alloys with very high alloying contents of chromium and molybdenum are suitable. Alloy 31 has been tested for such applications, both in the laboratory and directly in the plant, *inter alia* with specimens that were fixed to the agitating arms of acid digestion tanks as well as with tube specimens that were installed in the concentration units. As is evident from the results reproduced in **Table 4**, alloy

31 exhibits an attractive behavior in comparison with other materials that are commonly used for the production and processing of phosphoric acid. In fact, alloy 31 has proved its capabilities superbly under the particularly aggressive conditions of phosphoric acid production,<sup>29</sup> being probably the most cost-effective alloy to meet these harsh requirements<sup>30</sup> and having thus successfully replaced the higher-alloyed material alloy G-30 (cf. [Table 1](#)) in this application too.<sup>31</sup>

**Figure 12** Isocorrosion diagram of alloy 31 (EN 1.4562/UNS N08031) in slightly aerated technical grade sulfuric acid, determined by immersion tests over at least 120 h. Reproduced from Kirchheiner, R.; Wahl, V. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Ed.; Expert Verlag: Renningen, 2003; Chapter 8, pp 255–294.

According to the isocorrosion diagram in hydrochloric acid shown in [Figure 14](#), which was established on the basis of immersion tests,<sup>32</sup> alloy 31 is resistant at room temperature up to a concentration of 8% and at 80 °C up to a concentration of ~3% HCl. It may be inferred from this that alloy 31 should have good resistance in chemical processes in which traces of HCl can form.<sup>6</sup>

Alloy 31 (EN 1.4562/UNS N08031) has been tested in 67% boiling HNO<sub>3</sub> solution (Huey test). Even after 10 boiling periods of 48 h each, alloy 31 base material exhibits exceptionally low corrosion rates of 0.11 mm year<sup>-1</sup>, as shown by its position in [Figure 4](#). Notwithstanding its high Mo content, alloy 31 is therefore also outstandingly resistant in strongly oxidizing media.

Alloy 31 (EN 1.4562/UNS N08031) has also been tested under sour-gas conditions (10 bar H<sub>2</sub>S at 232 °C). In this test, the rate of uniform corrosion after 35 days was 0.01 mm year<sup>-1</sup> with no signs of pitting and stress-corrosion cracking at a load of 95% R<sub>p0.2</sub>. Alloy 31 complies with NACE specification MR-0175 (Level VI) and the requirements of the Exxon Slow Strain Rate Test (177 °C, 7 bar H<sub>2</sub>S, 980 MPa).<sup>33</sup>

The critical pitting corrosion temperature of alloy 31 is close to the upper 85 °C limit of the of the widely used FeCl<sub>3</sub> test.<sup>17</sup> Therefore, a direct comparison of the pitting corrosion resistance of alloy 31 with the pitting corrosion resistance of higher-alloyed nickel-base materials is better done by testing in a CaCl<sub>2</sub> test solution.<sup>34</sup> The results are demonstrated in [Figure 15](#). In this test, the critical pitting corrosion temperature

**Figure 13** Corrosion resistance of alloy 31 (EN 1.4562/UNS N08031) in sulfuric acid and its dependence on the presence of oxidants in the acid as shown by the position of the 0.1 mm year<sup>-1</sup> isocorrosion lines in aerated technical grade sulfuric acid and in analytical-grade (p.a.) sulfuric acid, as published by Alves *et al.* Reproduced from Alves, H.; Werner, H.; Agarwal, D. C. CORROSION 2006; NACE International: Houston, TX, 2006, Paper No. 06222.

<sup>a</sup>Temperature: 120 °C.**Figure 14** Isocorrosion diagram for alloy 31 (EN 2.4605/UNS N08031) in hydrochloric acid, determined by static immersion tests.<sup>14,32</sup>

of alloy 31 (EN 1.4562/UNS N08031) is at ~48 °C, well above the critical pitting corrosion temperature of alloy 625 (EN 2.4856/UNS N06625).

To obtain an initial indication of the relationship between temperature and pitting resistance in chloride-contaminated aqueous media, the pitting potential of alloy 31 (1.4562) was measured in ASTM artificial seawater.<sup>6</sup> The pitting potential is plotted against the temperature in **Figure 16** in comparison with the other two high-alloy materials, alloy 28 (EN 1.4563) and alloy 926 (EN 1.4529). Obviously, the potentials for the two reference materials fall sharply as the temperature rises, whereas for alloy 31 the pitting potential remains almost constantly high, even at temperatures up to 90 °C. This indicates outstanding resistance to pitting in actual media such as seawater, brackish water, and chloride-contaminated cooling water.

**Figure 15** Critical pitting temperatures (CPTs) in the CaCl<sub>2</sub> test as a function of the pitting resistance equivalent (PRE), according to Voigt *et al.*<sup>34</sup>

Besides its pitting resistance, the crevice corrosion resistance of alloy 31 in actual seawater service is also superior to that of the conventional 6% molybdenum steels such as EN 1.4529. As **Figure 17** shows,<sup>14</sup> when used as a flange material, the resistance limits are correspondingly broadened in the direction of higher temperatures and chlorine contents.

With regard to resistance to IC, the time–temperature–sensitization diagram plotted in the test according to ASTM G-28 Method A shows that sensitization in the sense of an intercrystalline 50 μm depth of penetration IC criterion only occurs after 2 h in the temperature range between ~650 and 700 °C.<sup>6</sup> To complement this, individual tests were also carried out on welded specimens (plate thickness

**Figure 16** Pitting potential of three high-alloy corrosion-resistant steels in ASTM seawater, agitated and air-saturated. Reproduced from Heubner, U. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Eds.; Expert Verlag: Renningen, 2003; Chapter 2, pp 47–93.

**Figure 17** Stability limits of alloy 926 (EN 1.4529/UNS N08926) when used as a flange material in chlorinated seawater up to the onset of crevice corrosion and their extension when using alloy 31 (EN 1.4562/UNS N08031), determined in tests in realistic conditions (North Sea, Norway), from Heubner. Reproduced from Heubner, U. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Eds.; Expert Verlag: Renningen, 2003; Chapter 1, pp 1–46.

6 mm) according to both ASTM G-28 Method A (120 h) and SEP 1877 Method II (24 h). The results are compared with those obtained for the two high-alloy special steels EN 1.4529 and EN 1.4563 in

**Table 5** Results of testing of TIG-welded alloy 31 (EN 1.4562/UNS N08031) specimens and reference materials in accordance with (a) ASTM G-28, Method A, 120 h, (b) testing in accordance with SEP 1877, Method II, 24 h. Surface ratio weld metal/base material of the corrosion specimens as 1:6, corrosion loss in millimeters per year, according to data taken from Heubner<sup>6</sup>

(a) ASTM G 28 A	Base material	Welded specimen
Alloy 926 (EN 1.4529)	0.43; 0.37	0.45; 0.58
Alloy 28 (EN 1.4563)	0.18; 0.14	0.20; 0.23
Alloy 31(EN 1.4562/UNS N08031)	0.18; 0.13	0.17; 0.20
(b) SEP 1877 II	Base material	Welded specimen
Alloy 926 (EN 1.4529)	0.13	0.24
Alloy 28 (EN 1.4563)	0.03	0.08
Alloy 31(EN 1.4562/UNS N08031)	0.04	0.05

**Table 5.** In both the tests, alloy 31 (1.4562) exhibits the lowest corrosion rates. The weld metal, HAZ and base metal are all free from IC. Hence, the IC resistance after welding that is required in actual service is guaranteed. It should be noted, however, that in the case of alloy 31 only the carbides that are precipitated at low temperatures manifest themselves in the form of sensitization; this is not the case with the sigma phase, which can form at high temperatures. Particularly after hot-forming work, which is critical for this, such as pressing of heads, a test for pitting resistance and notch impact toughness can indicate more readily than can an IC test whether the material is in perfect condition. This applies to welding as well.

The results of the corrosion tests and service experience to date indicate the following typical areas of application for alloy 31 (EN 1.4562/UNS N08031): equipment for production and the handling of phosphoric acid, pipes, and heat exchangers in contact with sulfuric acid and seawater, components for oil and natural gas extraction under sour-gas conditions, components for the pulp and paper industry, salt manufacturing industry, and, last but not least, flue gas desulphurization, where the use of alloy 31 is preferred especially for regulating and shut-off systems operating under extremely demanding conditions in modern coal-fired power stations. It is also qualified for the evaporation of effluents from flue gas cleaning (first evaporation stage).<sup>18</sup>

While alloy 31 (EN 1.4562/UNS N08031) has a wide-ranging scope for application, alloy 33

(EN 1.4591/UNS R20033) is suitable for specific applications. Although it was originally intended chiefly for use in oxidizing media in view of its high chromium content, it has also proven to be an attractive material for the handling of nonoxidizing acids and alkaline media and for use in chloride-containing aqueous solutions, for instance, seawater.

Alloy 33 exhibits lower corrosion rates in the passive state and a greater ease of passivation in 15–80% sulfuric acid at temperatures between 50 and 90 °C than do the traditional materials alloy 825 (EN 2.4858/UNS N08825) and alloy 20 (EN 2.4660/UNS N08020) that are well established for such applications. As a result, its range of use in the passive condition is broadened in comparison with these materials. Low oxidant contents enable the range of application to be extended to higher acid concentrations and temperatures. For example, as can

**Figure 18** Corrosion resistance of alloy 33 (EN 1.4591/UNS R20033) in stationary analysis-grade sulfuric acid of medium concentration for corrosion rates  $<0.13 \text{ mm year}^{-1}$  and various additions of  $\text{Fe}^{3+}$  as oxidant, added in the form of  $\text{Fe}_2(\text{SO}_4)_3$ , established using three parallel specimens in each case over a test period of 7 days. Reproduced from Heubner, U. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Ed.; Expert Verlag: Renningen, 2003; Chapter 2, pp 47–93.

be seen from the corrosion resistance diagram in **Figure 18**,  $\sim 6 \text{ mg l}^{-1} \text{Fe}^{3+}$  is sufficient to allow it to be used in conditions of up to 45%  $\text{H}_2\text{SO}_4$  and 80 °C, and  $\sim 28 \text{ mg l}^{-1} \text{Fe}^{3+}$  is sufficient in order to extend the range of application to 45%  $\text{H}_2\text{SO}_4$  and 90 °C.

In boiling 67% nitric acid (Huey test), alloy 33 exhibits a corrosion loss of only  $0.04 \text{ g m}^{-2} \text{ h}^{-1}$  in tests over  $15 \times 48 \text{ h}$ , and hence has the lowest level of corrosive attack of all known iron–nickel–chromium alloys under these corrosive conditions, as shown in **Figure 4**. On the basis of the results of extensive corrosion testing for up to 100 days, the alloy can be regarded as corrosion resistant, even in the welded state, at a  $\text{HNO}_3$  concentration of up to 95% at 25 °C, up to 90%  $\text{HNO}_3$  at 50 °C, up to slightly below 85%  $\text{HNO}_3$  at 75 °C, and in 67%  $\text{HNO}_3$  up to boiling point.<sup>13</sup> Alloy 33 is also of interest for handling nitric–hydrofluoric acid mixtures, as shown by the test results in **Tables 6** and **7**. It is therefore an attractive material not only for nuclear fuel reprocessing, but in particular for lining of pickling tanks for stainless steels.

The corrosion behavior of alloy 33 in highly concentrated sulfuric acid has been comprehensively tested.<sup>35–37</sup> **Figure 19** reproduces the isocorrosion diagram of alloy 33 for corrosion losses of 0.1 and 0.5 mm  $\text{year}^{-1}$  in stationary highly concentrated industrial-grade sulfuric acid according to the data given in Renner and Michalski-Vollmer.<sup>36</sup> It is evident that toward lower sulfuric acid concentrations, there are obviously two different corrosion mechanisms at work, depending on the temperature, which have their maximum reaction rates at  $\sim 110$  and  $\sim 190$  °C, respectively. However, under different test conditions and especially with a different test period, the situation may differ<sup>37</sup> from that shown in **Figure 19**, making the small window of corrosion resistance even narrower. Therefore, for practical applications, prior corrosion tests under the specific operating conditions are strongly advised.

It is not only in oxidizing acids and in reducing acids, whose composition has been sufficiently adjusted

**Table 6** Results of corrosion testing of alloy 33 (EN 1.4591/UNS R20033) and other materials for comparison in nitric/hydrofluoric acid solutions, immersion tests over 21 days at 90 °C, corrosion loss in grams per square meter per hour, according to data taken from Heubner<sup>6</sup>

<sup>a</sup>Duration of test: 7 days.

**Figure 19** Isocorrosion diagram for alloy 33 (EN 1.4591/UNS R20033) in stationary highly concentrated industrial grade sulfuric acid,<sup>6</sup> based on the data established by Renner *et al.*<sup>36</sup> over a test period of 21 days.

to oxidizing, that alloy 33 exhibits a corrosion behavior that is attractive for practical applications of many kinds; this also applies to alkaline media. For example, a corrosion loss of  $<0.01 \text{ mm year}^{-1}$  was measured in 25% and 50% caustic soda solution up to the boiling point.<sup>35</sup> Even for 70% caustic soda at 170 °C, a corrosion loss of only  $0.03 \text{ mm year}^{-1}$  is stated.<sup>38</sup> To complement this, field tests were carried out in NaOH tanks with added chlorine, the specimens therefore being exposed to both the liquid and the vapor phase. The material performed faultlessly, with only slight signs of crevice corrosion.<sup>6</sup> In a further field test with chloride- and chlorate-contaminated caustic soda from the diaphragm cell process, an outstanding resistance was measured,<sup>39</sup> as reported in Section 3.05.5.2.

The resistance of alloy 33 to pitting, which has been comprehensively tested<sup>34</sup> with regard to the handling of chloride-containing cooling water and use in seawater, is comparable with that of alloy 31 (EN 1.4562/UNS N08031), alloy 31 tending to

**Table 8** Critical pitting temperatures (CPT) and crevice corrosion temperatures (CCT), established in  $\text{FeCl}_3$  tests,<sup>34</sup> indicating the pitting resistance equivalent (PRE) as  $\% \text{ Cr} + 3.3 \times \% \text{ Mo} + 30 \times \% \text{ N}$

Alloy	EN	UNS	PRE	CPT (°C)	CCT (°C)
20	2.4660	N08020	28.3	15	<5
825	2.4858	N08825	33	30	<5
904L	1.4539	N08904	37	45	25
926	1.4529	N08926	47	70	40
33	1.4591	R20033	50	85	40
31	1.4562	N08031	54	>85	65

perform somewhat better. This is made clear by the results of the  $\text{FeCl}_3$  test shown in Table 8. In the  $\text{CaCl}_2$  test, on the other hand, both alloys have practically the same CPT, as is evident from Figure 15.

In terms of crevice corrosion resistance, on the other hand, alloy 33 (EN 1.4591/UNS R20033) is comparable with alloy 926 (1.4529/UNS N08926), as is again evident from Table 8. This confirms that higher nitrogen contents have a lesser effect on the crevice corrosion resistance than on the pitting resistance, in accordance with the data in Kirchheiner and Wahl<sup>17</sup> for the material EN 1.4565. Alloy 33 and alloy 926 can also be rated equally with regard to their repassivation potential in the case of crevice corrosion in seawater according to Voigt *et al.*<sup>34</sup> Combined with its high strength, excellent ductility, and high resistance to stress-corrosion cracking, even under sour-gas conditions,<sup>40</sup> possibilities for application in seawater and offshore service are therefore open to alloy 33.

In conclusion, it should be noted that alloy 33 (EN 1.4591/UNS R20033) exhibits a high degree of thermal stability. During ageing between 700 and 900 °C, its notch impact toughness decreases slightly because of precipitation of sigma phase, but nevertheless still exceeds 100 J even after a tempering time of 8 h. When tested for sensitization in boiling azeotropic nitric acid (Huey test), there are no signs of

either grain boundary attack or an increase in the rate of uniform corrosion even after tempering for up to 1000 h.<sup>35</sup>

### 3.05.3.7 Age-Hardenable Nickel–Chromium–Iron–Molybdenum (–Copper) Alloys

Positioned at the bottom of **Table 1** is an alloy group consisting of two important age-hardenable nickel–chromium–iron–molybdenum (–copper) alloys. They are used for bars, tools, pump shafts, valves, and forgings in oil and gas production where low weight and hence high strength is a requirement. Their high mechanical strength is achieved by so-called age-hardening in an intermediate range of temperatures where intermetallic phases are precipitating within the metallic matrix, causing an increase of strength. Alloy 925 (EN 2.4852/UNS N09925) is the age-hardenable version of alloy 825 (EN 2.4858/UNS N08825), with an almost identical corrosion behavior (cf. **Section 3.05.3.6.2**). Alloy 718 (EN 2.4668/UNS N07718), however, has its origin in high temperature/high-strength applications and has been adapted very successfully for the wet corrosive requirements of oil and gas extraction.

## 3.05.4 Corrosion Behavior of Nickel Alloys in the Welded State

### 3.05.4.1 The Specific Surface and Structural Condition of the Weld Metal and the HAZ

In chemical, environmental, power, and marine engineering, welding is the most popular joining method. In these fields, there are very few material applications where welding is not required. The corrosion resistance that is determined for a material in its various mill product forms should therefore generally apply to this material in the welded state as well, that is, to the weld metal and the whole area of the weld. The weld area of a construction may well be the location of preferential corrosive attack, because here – in contrast to the homogeneous solution-annealed or stabilized and subsequently (if necessary) shot-blasted and pickled state – a clean, bright metal surface may not be obtained easily. Instead, the weld may have slag residues or may be oxidized depending on the welding process used. The adjacent HAZ is also likely to be coated with surface oxides to varying extents, which are generally recognizable as temper colors. A lookout should also be kept for spatter and contamination away from the weld, which are usually

detrimental to corrosion resistance. Moreover, in the weld area the microstructure is heterogeneous not only in the weld metal with its cast structure, but often also in the HAZ directly adjoining the weld. The extent of the structural changes caused by the welding operation in the HAZ depends on the material and its susceptibility to precipitation of carbides and intermetallic phases at medium temperatures, as well as on the heat input and the rate of cooling during welding. Problem-free welding of a material by means of the particular welding process is only possible if welding techniques and welding parameters can be used to keep the heat input so low that the agreed testing methods fail to discover any intolerable structure-related impairment of the corrosion behavior and the mechanical properties in the HAZ. Moreover, care should be taken where necessary to ensure, by appropriate posttreatment of the surface, that any scale and any surface oxides manifesting themselves as temper colors do not adversely affect the material's corrosion behavior.

Some possible defects in the weld area are depicted schematically in **Figure 20**. Slag residues

**Figure 20** Possible defects in the weld area and their effects on corrosion behavior, from Heubner. Reproduced from Heubner, U. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, et al., Ed.; Expert Verlag: Renningen, 2003; Chapter 2, pp 47–93.

on the surface of the weld are sites of preferential attack, because they offer ideal conditions for crevice corrosion and pitting. The same applies to pores, which, in the form of solidification porosity, cannot be ruled out for nickel alloys, but can be controlled by alloying techniques with respect to the filler metal or by other welding engineering measures. An excessively rough material surface (ribbed texture), edge misalignment, or severe cases of drop-through chiefly allow room for the formation of sediments, deposits, and incrustations, which, acting like a sponge, result in local concentrations of corrosive media constituents such as chloride ions that can lead to localized corrosion. Solidification cracks, hot cracks, weld undercuts, weld interface, and root cracks and incomplete root fusion are ideal locations for crevice corrosion attack. With materials that require a higher-alloyed filler metal, unmixed fusion zones in the root area, but also on the capping pass side, can be sites of preferential corrosive attack. High mechanical stresses in the weld area, including thermally caused stresses, may result in an increased likelihood of stress-corrosion cracking, depending on the material and the surrounding medium. A rough-ribbed structure of the weld metal can also contribute to this on account of the stress peaks, which then arise.

#### 3.05.4.2 Surface Condition and Necessary Surface Treatment after Welding

Oxide layers on the weld metal and oxides over the HAZ, which manifest themselves as temper colors, weaken the resistance of nickel alloys to pitting. As known from stainless steels,<sup>6</sup> the differences in corrosion resistance may be greatest between pickled surfaces and those with 'light,' that is, straw-yellow temper colors. As temper colors become darker, corrosion resistance further decreases. The surface oxide layers either consist almost exclusively of chromium oxide,  $\text{Cr}_2\text{O}_3$  (spinel type)<sup>41</sup> or are, at any rate, generally significantly enriched with chromium.<sup>42</sup> The chromium required for oxide formation is extracted from the matrix of the material, which consequently becomes depleted in chromium. As the resistance of nickel–chromium–molybdenum alloys to pitting is almost exclusively determined by their chromium and molybdenum contents, a decrease in the chromium content is synonymous with reduced resistance to this type of corrosion.<sup>41</sup> There is even a strong possibility that immediately beneath the oxide coating, there is a thin metallic surface layer, which no

longer corresponds to the intended material grade at all. Therefore, it is understandable that in such a case, simply removing the temper colors may not be sufficient to restore the resistance of the unwelded base material; it may in fact be necessary to remove the chromium-depleted metallic surface layer lying immediately beneath them at the same time. In practice, the situation may become really problematic, for the technical corrosion resistance of a material depends less on the pitting potential than on the lower repassivation potential, because it is only below this repassivation potential that pitting, once begun, can be stopped again.

In industrial engineering practice, therefore, full-immersion pickling of welded components is recommended for critical situations. This, however, is feasible only in certain cases and to a limited extent. Moreover, its success depends on the material and on the pickling method employed. As a rule, it is necessary to use a different means for removing the surface oxides. In modern fabrication practice, the methods of *in situ* pickling of the component, abrasive blasting, and grinding are mainly used. The effectiveness of each of these measures was investigated by, among other things, measuring the critical pitting potential in artificial seawater.<sup>43,44</sup> It turned out that, among the methods of grinding with disc wheels, blasting with glass beads and pickling with  $\text{HNO}_3/\text{HF}$  pickling pastes, grinding was the least effective – at least with a very rough finish – and the best results were obtained with the pickling pastes. For the some types of stainless steels, the results of the investigation show that when using the pickling pastes, it is at best possible to obtain a corrosion resistance that is virtually equivalent to that of the metal in the bright, unwelded state. On the other hand, in the case of higher-alloyed materials such as alloy 625 (EN 2.4856/UNS N06625), there was only a slight dependence of the corrosion resistance on the method of surface treatment. With this material, the pickling action achieved was insufficient to remove not only the oxide coating but also an adequate amount of the chromium-depleted metallic surface layer beneath it, because even in a chromium-depleted surface condition, this material is too corrosion-resistant in relation to the pickling agent for this to be achieved within the treatment time. This is true not only of treatment with pickling paste, but has also been observed with nickel–chromium–molybdenum alloys in the case of post-treatment by immersion or spray pickling.

Consequently, brushing of welds with a stainless steel wire brush immediately after welding while

the metal is still hot, at the least, is vital in order to remove surface contamination, slag residues, and temper colors to the greatest possible extent. Subsequent pickling is then likely to produce a further marked improvement in corrosion resistance, but mechanical removal of the chromium and molybdenum-depleted metallic surface might be an additional requirement in case of very corrosion-resistant materials when used near to the limit of their corrosion resistance. The highest resistance to pitting is obtained with electrochemical polishing. If there are doubts regarding the nature and extent of postweld treatment, the testing of expertly executed and experimentally posttreated welded joints in a manner which corresponds or at least approximates to the level of corrosive attack in practice is essential.

### 3.05.4.3 IC in the HAZ

In chromium-alloyed nickel-base materials, with a sufficiently high carbon content of the HAZ adjacent to a welded joint, preferential precipitation of chromium carbides at the grain boundaries may occur, with the consequence of chromium depletion in the region near the grain boundaries. This may go so far that under corrosive attack, adequate corrosion resistance no longer exists in this region, and IC occurs. This can also take the form of pitting along the grain boundaries; it is then referred to as sensitization. In the case of the chromium-alloyed nickel-base materials for wet-corrosion service that are the focus of interest here, only LC grades or stabilized materials are in use today; as a result, IC, owing to simple precipitation of chromium carbide, only rarely comes up for discussion in the case of these materials—for instance, if it is necessary to consider a high temperature material with a high carbon content, such as the nickel–chromium alloy 600 (EN 2.4816/UNS N06600) with regard to temporary service under wet-corrosion conditions (e.g., shutdown dew point corrosion and during cleaning) among other factors.

However, in the case of the chromium-alloyed nickel-base materials, IC in the HAZ of welded joints may well be a matter, which requires consideration owing to the precipitation of intermetallic phases, including the  $M_6C$  type of carbide. On the other hand, the sigma phase, which is precipitated in, for example, the nickel–chromium–iron–molybdenum–copper alloy 31 (EN 1.4562/UNS N08031) in the medium temperature range<sup>45</sup> leads, when tested in the conventional tests according to ASTM G 28 A or SEP 1877 II, not to IC but to an increased

susceptibility to pitting;<sup>46</sup> however, this does not usually cause problems in fabrication by welding.

Figure 11 shows a summary of the time–temperature–sensitization diagrams that have been plotted for nickel–chromium–molybdenum alloys.

Leaving aside the more stringent Strauss test, which is little used, the test methods employed for IC testing of high-alloyed materials range from the Huey test, which specifies very strongly oxidizing conditions, *via* the Streicher test in accordance with ASTM G 28 A, which likewise specifies oxidizing conditions, to – with decreasing aggressiveness – the testing of nickel–molybdenum alloys in hydrochloric acid. However, there is no standardized method of IC testing for slightly oxidizing conditions, which would be typical of the corrosive conditions to which nickel–chromium–molybdenum alloys are frequently exposed, for example, in the aqueous media encountered in FGD plants of fossil-fired power stations. To fill this gap, the anodic polarization behavior of welded nickel–chromium–molybdenum alloys in solutions containing sulfuric acid with the addition of anions with a structure-specific effect, such as  $SCN^-$  and  $Cl^-$ , was investigated.<sup>47</sup> The results showed that in the transitional active/passive range of the materials, it is actually possible to distinguish between the behavior of different heat treatment states with regard to IC of the HAZ and pitting-like selective corrosion of the weld metal, which also occurs under these test conditions. In such a test, after welding with a heat input in excess of  $8 \text{ kJ cm}^{-1}$ , the tendency for increased IC within the HAZ and for selective corrosion of the weld metal is most marked in the case of alloy C-276, followed by alloy C-4. With the alloy 59 (2.4605), any influence of the heat input during welding only becomes noticeable if the values for the energy inputs per unit length of weld are as extreme as  $6.2 \text{ kJ cm}^{-1}$  on the one hand, or  $15.1 \text{ kJ cm}^{-1}$  on the other. In this respect too, therefore, alloy 59 (EN 2.4605/UNS N06059) proves to be the least susceptible nickel–chromium–molybdenum alloy.

### 3.05.4.4 Resistance of Weld Metal and Heat Affected Zone to Pitting

The cast structure of the weld metal and the associated segregations have widely differing effects on corrosion resistance, depending on the material and the surrounding medium. Because of this, unalloyed nickel and the nickel–copper, nickel–molybdenum, and nickel–chromium alloys are welded with fillers of identical or at least similar composition to the base

metal; here, peculiarities in the chemical composition of the filler metals have more to do with the technical requirements of the welding operation than with the demands of corrosion resistance.

If nickel–chromium–molybdenum alloys are welded with filler of identical composition to the base metal, practical experience clearly shows that the identical-composition weld metal generally has the same high corrosion resistance, in spite of its heterogeneous nature,<sup>22</sup> as the homogeneous austenitic base metals, at least below certain threshold conditions of attack. Electrochemical tests in oxidizing ASTM G-28 A solution have revealed only minor differences, the weld metal, in fact, having a more noble corrosion and passivation potential.<sup>48</sup> Potential profiles relating to joint welding of nickel–chromium–molybdenum alloys with filler of the same composition as the base metal show no or only slight differences between the wrought alloy and the weld metal.<sup>49</sup> However, marked differences arise in the testing of the pitting resistance. For instance, in the ‘Green Death’ test<sup>23</sup> the CPT established for the weld metal of FM 625 (EN 2.4831/UNS N06625) was on average  $\sim 12$  K lower than that established for the corresponding homogeneous austenitic material alloy 625 (EN 2.4856/UNS N06625), and for the weld metal of FM C-276 (EN 2.4886/UNS N10276) the CPT was on average  $\sim 18$  K lower than that of the corresponding homogeneous austenitic material alloy C-276 (EN 2.4819/UNS N10267).<sup>23</sup> In the  $\text{CaCl}_2$  test,<sup>23</sup> which is more sensitive and can be used over a wider range of alloys, this difference is on average c. 25 K for alloy C-276 (EN 2.4819/UNS N10267).<sup>23,50</sup> If the actual conditions of service make it necessary to do so, for example, as a result of realistic tests in the chloride/pH/temperature matrix (cf. Figure 9), it is probable, based on the test results available so far,<sup>22,23</sup> that the reduced corrosion resistance of the weld metal of FM 625 and FM C-276, as shown by the ‘Green

Death’ test,<sup>23</sup> can be avoided by instead using FM 59 (EN 2.4607/UNS N06059) as filler metal.

A good guide to the anticipated behavior of materials on welding is also given by cooling tests at different rates from the solution-annealing temperature.<sup>46</sup> Table 9 shows the results obtained from tests with alloy 31 (EN 1.4562/UNS N08031). This alloy should preferably be solution-annealed at 1150–1180 °C. If the CPT in the HAZ, to be measured in the  $\text{FeCl}_3$  test, must not fall below 75 °C, the cooling rate in the range between the solution-annealing temperature and 600 °C should, according to these test results, be at least 150 °C  $\text{min}^{-1}$ . The associated notch impact energy values, which are often of interest to the design engineer, are also shown in Table 9 for comparison. It is interesting to note that in this case the notch impact energy does not fall in parallel with the pitting resistance, but initially rises; this has been observed, to a far greater extent, with alloy 926 (EN 1.4529/UNS N08926) as well in the case of isothermal ageing.<sup>51</sup>

### 3.05.5 Application of Nickel and Nickel Alloys as Materials Resistant to Aqueous Corrosion in the CPI and in Environmental Technology

#### 3.05.5.1 General

The CPI and environmental technology have to cope with a large variety of adverse operating conditions, including a wide range of temperatures, all kinds of static and dynamic loads, as well as numerous solid, liquid, and gaseous products and product mixtures. Safety, cost-efficiency, and even the feasibility of a process depend on whether the materials envisaged for the plant and its components can handle the required range of different operating conditions.

Nickel and nickel alloys are needed in all areas of halogen chemistry/chlorine chemistry to withstand both general and localized forms of corrosion. Further applications can be found in chemical processes involving alkalis (e.g., caustic soda) or acids (e.g., sulfuric acid and acetic acid) at different concentrations and temperatures. These high corrosion-resistant materials are well established in wide areas of chemical processing, and in the following section, some selected examples of their application are presented.

Beyond the scope of the CPI and environmental technology, nickel alloys are finding wet corrosive applications in many other industrial sectors, for example, marine technology<sup>14</sup> and oil and gas extraction.<sup>28,33</sup>

**Table 9** Influence of the cooling rate from the solution-annealing temperature down to 600 °C on the CPT to be measured in the  $\text{FeCl}_3$  test and the notch impact energy ( $A_v$ ) of alloy 31 (EN 1.4562/UNS N08031)<sup>6,46</sup>

Condition	CPT (°C)	$A_v$ (J)
Solution-annealed	85	266
At 150 °C $\text{min}^{-1}$ to 600 °C	75	270
At 50 °C $\text{min}^{-1}$ to 600 °C	70	280
At 25 °C $\text{min}^{-1}$ to 600 °C	55	240

### 3.05.5.2 Production of Caustic Soda

Caustic soda (NaOH) is one of the most important chemical feedstocks, with a total annual production of  $10^6$  tons. NaOH is used in organic chemistry, in the production of aluminum, in the paper industry, in the food processing industry, in the manufacture of detergents, etc. Caustic soda is a coproduct in the production of chlorine, 97% of which takes place by the electrolysis of sodium chloride.

Caustic soda has an aggressive impact on most metallic materials, especially at high temperatures and concentrations. It has been known for a long time, however, that nickel exhibits excellent corrosion resistance to caustic soda at all concentrations and temperatures, as shown by **Figure 1**. In addition, except at very high concentrations and temperatures, nickel is immune to caustic-induced stress-corrosion cracking. The nickel standard grades alloy 200 (EN 2.4066/UNS N02200) and alloy 201 (EN 2.4068/UNS N02201) are therefore used at these stages of caustic soda production, which require the highest corrosion resistance. The cathodes in the electrolysis cell used in the membrane process are made of nickel sheets as well. The downstream units for concentrating the liquor are also made of nickel. They operate according to the multistage evaporation principle mostly with falling-film evaporators. In these units, nickel is used in the form of tubes or tube sheets for the preevaporation heat exchangers, as sheets or clad plates for the preevaporation units, and in the pipes for transporting the caustic soda solution. Depending

on the flow rate, the caustic soda crystals (super-saturated solution) can cause erosion on the heat exchanger tubes, which makes it necessary to replace them after an operating period of 2–5 years. The falling-film evaporator process is used to produce highly concentrated, anhydrous caustic soda. In the falling-film process developed by Bertrams, molten salt at a temperature of  $\sim 400^\circ\text{C}$  is used as the heating medium. Here, tubes made of low-carbon nickel alloy 201 (EN 2.4068/UNS N02201) should be used, because at temperatures higher than  $\sim 315^\circ\text{C}$  ( $600^\circ\text{F}$ ), the higher carbon content of the standard nickel grade alloy 200 (EN 2.4066/UNS N02200) can lead to graphite precipitation at the grain boundaries. Nickel is the preferred material of construction for caustic soda evaporators where the austenitic steels cannot be used. In the presence of impurities such as chlorates or sulfur compounds – or when higher strengths are required – chromium-containing materials such as alloy 600 L (EN 2.4817/UNS N06600) are used in some cases. Also of great interest for caustic environments is the high-chromium-containing alloy 33 (EN 1.4591/UNS R20033). If these materials are to be used, it must be ensured that the operating conditions are not likely to cause stress-corrosion cracking. Alloy 33 (EN 1.4591/UNS R20033) exhibits excellent corrosion resistance in 25% and 50% NaOH up to boiling point and in 70% NaOH at  $170^\circ\text{C}$ . This alloy also showed excellent performance in field tests in a plant exposed to caustic soda from the diaphragm process.<sup>39</sup> **Figure 21**

**Figure 21** Corrosion rates of alloy 33 (EN 1.4591/UNS R20033) and low carbon nickel alloy 201 (EN 2.4068/UNS N02201) after almost 3 months of exposure to diaphragm caustic soda contaminated with NaCl, Na<sub>2</sub>CO<sub>3</sub>, and NaClO<sub>3</sub> in various ranges of concentrations and temperatures. Reproduced from Alves, H.; Horn, E. M.; Klöwer, J. In *Nickel Alloys and Special Stainless Steels*; 3rd ed.; Heubner/Klöwer, *et al.*, Ed.; Expert Verlag: Renningen, 2003; Chapter 7, pp 226–254.

shows some results regarding the concentration of this diaphragm caustic liquor, which was contaminated with chlorides and chlorates. Up to a concentration of 45% NaOH, the materials alloy 33 (EN 1.4591/UNS R20033) and nickel alloy 201 (EN 2.4068/UNS N02201) show a comparable outstanding resistance. With increasing temperature and concentration, alloy 33 becomes even more resistant than nickel. Thus, as a result of its high chromium content, alloy 33 seems to be advantageous to handle caustic solutions with chlorides and hypochlorite from the diaphragm or mercury cell process.

### 3.05.5.3 Production and Handling of Sulfuric Acid

Sulfuric acid ( $\text{H}_2\text{SO}_4$ ) is one of the basic raw materials for the chemical industry. It is used in numerous processes as a reagent, as a catalyst, and as a drying agent. Examples of the wide-ranging applications of this acid include the treatment of raw phosphates in the fertilizer industry, the treatment of titanium ores for the production of titanium dioxide, the manufacture of phosphoric and hydrofluoric acid, and the wide field of organic chemical synthesis, for example, in sulfonation and nitration.

Today, primarily elemental sulfur but also pyrite is used as raw material for the production of sulfuric acid. Combustion produces sulfur dioxide ( $\text{SO}_2$ ) which is subsequently converted catalytically to form sulfur trioxide ( $\text{SO}_3$ ) and thereafter is absorbed in concentrated sulfuric acid, usually in several stages. The absorption of  $\text{SO}_3$  in concentrated sulfuric acid takes place in packed towers. Absorption occurs in a counter-current system, the  $\text{SO}_3$  gas flowing upwards and the concentrated sulfuric acid flowing downwards. This process is highly exothermic.

So far, only a few materials were available which offer adequate corrosion resistance to highly concentrated sulfuric acid at high temperatures. As a result, the operating temperatures for the downstream equipment such as heat exchangers, pumps, and piping had to be reduced. For components operating at these lower sulfuric acid temperatures, various special materials are used. The nickel alloy C-276 (EN 2.4819/UNS N10276) is used for plate-type heat exchangers serving as acid coolers. Alloy 59 may also be used for this purpose. The isocorrosion diagram of alloy C-276 in technical grade sulfuric acid (Figure 5) at its extreme high concentration side on the right shows a large horizontal distance between the 0.1 and the 0.5 mm year<sup>-1</sup> isocorrosion

line, indeed. This represents an excellent safety margin in case of temporary excursions of the sulfuric acid to lower concentrations.

Alloy 33 (EN 1.4591/UNS R20033) had been developed with the aim to use it, for example, for large acid distribution systems and plate heat exchangers.<sup>36</sup> Figure 19 shows the isocorrosion diagram for this material in highly concentrated sulfuric acid. However, it must be emphasized that sulfuric acid can exhibit very complex behavior toward materials. For example, the temperature dependence of the corrosion rate of alloy 33 in highly concentrated sulfuric acid is not monotonous.<sup>36,37</sup> For certain acid concentrations, it is possible to cause the corrosion rate to rise by decreasing the temperature, an effect which can be observed in the isocorrosion diagram of Figure 19. Furthermore, traces of impurities, changes in the rate of flow, slight changes in concentration and/or slight increases in temperature can cause markedly higher rates of corrosion. In view of this, the isocorrosion diagram presented in Figure 19 can only serve to provide an initial orientation and extensive testing in the actual plant acid and environment is necessary when selecting alloy 33 (EN 1.4591/UNS R20033).

Depending on the actual operating conditions, deviations can be expected to occur to a lesser or greater extent. This is true not only for the highly concentrated sulfuric acid discussed here in detail but for the whole range of sulfuric acid concentrations as shown in Figures 5, 6, and 12, in particular for those temperatures under which materials are near their limits of resistance. If the operating parameters cannot be closely controlled, it may, in some cases, be necessary to select a material not as a function of its resistance to the theoretical operating conditions, but rather because of its ability to absorb variations in these conditions. As is so often the case, only plant testing under true service conditions is likely to give a reliable indication on the suitability of materials in most circumstances.

With these considerations in mind, the handling of sulfuric acid and sulfuric acid-based aqueous solutions constitutes a very broad field of application for nickel alloys. Standard stainless steel grades can be used only to handle much diluted acid at low temperatures. At higher concentrations and temperatures, the use of materials like high-alloy stainless steels and nickel alloys becomes necessary. Alloy 20 (EN 2.4660/UNS N08020), alloy 825 (EN 2.4858/UNS N08825), alloy 31 (EN 1.4562/UNS N08031), alloy 59 (EN 2.4605/UNS N06059), and alloy B-2 (EN 2.4617/UNS N10665) are some examples.

As pointed out in [Section 3.05.3.3](#), the use of alloy B-2 may become necessary at sulfuric acid concentrations between 60% and 80% and temperatures even above 120 °C, but clearly reducing conditions must be present.

The use of the alloys 825 and 20, on the other hand, is restricted to the lower temperature range, but is facilitated by the presence of oxidants, as mentioned in [Section 3.05.3.6.2](#). The newer alloys 31 (EN 1.4562/UNS N08031) and 59 show a more extended suitability. This is obvious from their isocorrosion diagrams in technical grade aerated sulfuric acid shown in [Figure 6](#) for alloy 59 (EN 2.4605/UNS N06059) and in [Figure 12](#) for alloy 31 (EN 1.4562/UNS N08031). However, it has to be kept in mind that the 0.1 mm year<sup>-1</sup> isocorrosion line of alloy 31 in sulfuric acid is shifted to lower temperatures if no oxidants are present as demonstrated in [Figure 13](#) with the comparison of the corrosion behavior in technical grade sulfuric acid and in a p.a. sulfuric acid, established by Alves *et al.*<sup>20</sup> Although oxidants can extend the region of passivity of alloy 31, the corrosion behavior of alloy 59 is not influenced greatly by the amounts of oxidants present in the acid.<sup>20</sup>

Besides the influence of oxidants, the influence of the temperature deserves a closer look, too. Near the isocorrosion line, temperature is an extremely important variable influencing the corrosion rate, since above that line corrosion rate rises above 0.1 mm year<sup>-1</sup> and materials may become unsuitable for service. Alloy 31 (EN 1.4562/UNS N08031) and alloy 59 (EN 2.4605/UNS N06059) behave differently in this respect. While for alloy 31, a small temperature

increase above the isocorrosion line can cause a jump in corrosion rate, for alloy 59 the corrosion rate also increases but more moderately, as shown in [Figure 22](#). This is because the corrosion rate in active state, which depends directly on the test temperature and on the alloy composition, is significantly higher for alloy 31 than for alloy 59. Particularly, high Ni and Mo contents are known to reduce the rate of active current density giving rise to the lower active corrosion rates of alloy 59.<sup>20</sup> Anodic polarization curves, which had been established in this context by Alves *et al.*,<sup>20</sup> indicate that alloy 31 is not so easy to passivate as alloy 59, but once passive, it exhibits lower passive current density than does alloy 59. This is probably related to the copper content of alloy 31 (EN 1.4562/UNS N08031), since copper is known to influence the passive current density in sulfuric acid.<sup>20</sup>

In many sulfuric acid applications, chlorides are also present, for example, in wall condensate in FGD units. Chlorides impair the corrosion resistance in sulfuric acid in shifting the anodic curve to higher current densities, making passivation more difficult, increasing the corrosion rates and may produce pitting corrosion. Indeed, as shown by Alves *et al.*,<sup>20</sup> the 0.1 mm year<sup>-1</sup> isocorrosion line of alloy 31 (EN 1.4562/UNS N08031) is shifted to significantly lower temperatures when 1 g l<sup>-1</sup> chloride is added to the sulfuric acid. However, in sulfuric acid contaminated with chlorides, alloy 59 (EN 2.4605/UNS N06059) has advantages over alloy 31, as exemplified in [Figure 23](#), and its resistance to pitting is higher.

Many chemical processes use 98–99% sulfuric acid. After reaction is completed, the acid is not totally consumed, but is discharged in a diluted and

**Figure 22** Corrosion rates of alloy 31 (EN 1.4562/UNS N08031) and of alloy 59 (EN 2.4605/UNS N06059) in aerated technical grade sulfuric acid closely below and above the 0.1 mm year<sup>-1</sup> isocorrosion line, 24 h immersion test, according to Alves *et al.*<sup>20</sup>

**Figure 23** Corrosion rates of alloy 31 (EN 1.4562/UNS N08031) and of alloy 59 (EN 2.4605/UNS N06059) in aerated technical grade sulfuric acid with addition of 1.5% chloride, graph published by Alves *et al.*<sup>20</sup>

contaminated form. This waste acid is totally useless unless it can be concentrated (e.g., up to 75–80%) and purified for further use in chemical process reactions. Both alloy 31 (EN 1.4562/UNS N08031) and alloy 59 (EN 2.4605/UNS N06059) are in use in the regeneration of waste sulfuric acid.

For example, in viscose Rayon plants, alloy 31 (EN 1.4562/UNS N08031) is used in the regeneration of sulfuric acid. In the spinning step, the viscose is forced through a spinneret to produce the fine filaments and then comes into contact with a solution of sulfuric acid, sodium sulfate, and usually  $\text{Zn}^{2+}$  ions. The waste sulfuric acid from this step is regenerated by condensation under vacuum at temperatures between 30 and 40 °C and further adjusted with highly concentrated sulfuric acid, the dissociation heat of which can raise the temperature to up to 60 °C. The resulting 80–85% acid can be used for further processes.

In the production of titanium dioxide by the sulfate process, finely ground ilmenite ( $\text{FeTiO}_3$ ) or ilmenite slag is digested with sulfuric acid in a concentration of ~90% and the cleaned titanium oxide sulfate is hydrolyzed to form titanium oxide hydrate, which is then calcined to form  $\text{TiO}_2$ . Modern plants incorporate a downstream dilute sulfuric acid processing facility. Alloy 31 (EN 1.4562/UNS N08031) is used in this application.

Further examples of waste acid recovery systems can be found in the metal-producing industry. In the copper production, alloy 31 (EN 1.4562/UNS N08031) is used in autoclaves to concentrate spent waste-contaminated sulfuric acid from 25% to ~75–80% in evaporators under vacuum. The

presence of oxidizing metal ions in the contaminated acid helps maintain the passivity of alloy 31 (EN 1.4562/UNS N08031).

### 3.05.5.4 Production of Phosphoric Acid

A large amount of the world's fertilizer production is based on phosphoric acid ( $\text{H}_3\text{PO}_4$ ). Two principal production methods are used. Thermal phosphoric acid is produced by the combustion of phosphorus with atmospheric oxygen, followed by the hydration of the oxide obtained. Owing to its high purity, this acid is primarily used as a food additive. Because of the high energy requirement, this method is of secondary importance. In the wet process, phosphoric acid is produced by digesting phosphate rock (apatite), usually with sulfuric acid. The by-products of this process are calcium sulfate, in the form of dihydrate (gypsum), and fluosilicic acid. About 95% of the global demand for phosphoric acid is met by the wet process. After filtration, the phosphoric acid, usually at a concentration of ~28%  $\text{P}_2\text{O}_5$ , is concentrated either to the standard commercial grade of 54%  $\text{P}_2\text{O}_5$  or to super phosphoric acid with 70%  $\text{P}_2\text{O}_5$ .

The action of phosphoric acid on most metals is not particularly aggressive. However, the sulfuric acid and the presence of fluorine, chloride, and silica in the phosphate ores, which leads to the formation of hydrofluoric acid, fluosilicic acid, and also hydrochloric acid, give rise to very complex corrosion conditions. Silica and aluminum are used to complex with fluorine and reduce its corrosive effect. The chloride concentration strongly depends on the origin of the apatite and increases if the ores are washed using

seawater. Corrosiveness is further increased by the presence of sulfides. In addition, the degree of corrosive attack is aggravated by erosion resulting from the presence of abrasive solids such as phosphate rock particles and gypsum crystals, by turbulence and high velocity fluid flow, by deposit formation and by increases in temperature. From literature and plant experience, it is known that high chromium levels in the alloys used are required for sufficient corrosion resistance to phosphoric acid under those conditions.

In the wet process, the first stage for which corrosion-resistant materials are required is the reactor for digesting the ore. The reactor vessel is made of carbon steel throughout with a nonmetallic lining, sometimes augmented with acid-resisting bricks, particularly in locations of impingement and abrasion. The agitators are often made of special stainless steels. The application of these alloys, however, is limited by the increasing impurities in the phosphate ores and higher temperatures for digesting the ore. Experience gained under real service conditions proved that the materials alloy 31 (EN 1.4562/UNS N08031) and alloy 625 (EN 2.4856/UNS N06625) are particularly resistant to erosion and corrosion in phosphoric acid slurries.<sup>29</sup>

The filtration equipment requires special materials, in particular, with good resistance to pitting and crevice corrosion. The materials used for this equipment item are high-alloy stainless steels, but higher resistance to pitting and crevice corrosion can be achieved with alloy 31 (EN 1.4562/UNS N08031).

After filtration, the raw phosphoric acid, which may be contaminated with sulfuric acid, chlorides, fluorides, and fluosilicic acid, is concentrated to 54%  $P_2O_5$ . This takes place in an evaporator that is either equipped with metal tubes or is made of graphite. It has been shown that metallic heat exchangers

operate satisfactorily when hot water is used as the heating medium. The solids settling on the tube walls, mainly gypsum, are easily removed by routine cleaning, which prevents corrosion under the deposits. Alloy 28 (EN 1.4563/UNS N08028) and alloy 31 (EN 1.4562/UNS N08031) are used for the heat exchangers.

In the further processing to produce super phosphoric acid (70–72%  $P_2O_5$ ), usually no particular corrosion problems arise, because most of the fluorine contaminants have been removed in the upstream stages. The nickel–chromium–molybdenum alloy 625 (EN 2.4856/UNS N06625) is the standard material here. Nickel alloys are also used for further equipment in the phosphoric acid production, such as plate heat exchangers, equipment for the removal of gaseous fluorine compounds, pumps, and fans.

According to [Table 4](#), alloy 31 (EN 1.4562/UNS N08031) exhibits high resistance to uniform and localized corrosion in industrial phosphoric acid under diverse conditions.<sup>29</sup> In phosphoric acid contaminated with sulfuric acid, fluosilicic acid, oxidizing metallic ions, and high amount of chlorides at 80 °C, this alloy shows outstanding corrosion resistance. At 120 °C, the corrosion rate becomes considerably higher. At these high temperatures, contamination is extremely important and must be well defined and controlled. In the example of [Table 4](#), the contaminated 52% phosphoric acid at 120 °C is ~10 times more corrosive than is the technical pure one.

It should be emphasized that the performance of alloy 31 (EN 1.4562/UNS N08031), which combines a high chromium content with a sufficient molybdenum level is comparable or even many times superior to higher-alloyed materials of significantly higher price. As an example, [Figure 24](#) shows the corrosion rate of various alloys in attack acid with different

**Figure 24** Corrosion rate of various alloys upon immersion in attack acid with (mass%) 33  $P_2O_5$ , 1.6  $SO_3$ , 1.8 F, and different chloride content at 90 °C.

chloride content at 90 °C, demonstrating that alloy 31 excels with the lowest corrosion rate.<sup>30,52</sup> This alloy also resists well to erosion–corrosion conditions,<sup>29</sup> which is in accordance with studies suggesting that under the mixed erosion–corrosion conditions found in the phosphoric acid industry, it is primarily corrosion resistance rather than hardness that determines the performance of the material. Typical applications for alloy 31 (EN 1.4562/UNS N08031) in phosphoric acid production include mixers, filter components, piping systems, heat exchanger tubes in concentration units, sulfuric acid coolers, vapor systems in concentration plant, flash coolers, and others. In particular, the use of alloy 31 (EN 1.4562/UNS N08031) in phosphoric acid production increases feedstock flexibility by contributing in a cost-effective manner to the solution of corrosion problems in the processing of, for example, phosphate ores containing high levels of chlorides.<sup>30,31</sup> Additional information on suitable alloys for application in phosphoric acid and on tackling chloride corrosion in phosphoric acid production is provided by Alves *et al.*<sup>52</sup> and by Hoxha *et al.*<sup>53</sup>

### 3.05.5.5 Production of Hydrofluoric Acid and Aluminum Fluoride

Hydrofluoric acid (HF) is produced by the reaction of concentrated sulfuric acid with fluorspar (calcium fluoride):  $\text{CaF}_2 + \text{H}_2\text{SO}_4 \rightarrow 2 \text{HF} + \text{CaSO}_4$ . The reaction can take place in two stages. In the first stage, preheated fluorspar and preheated sulfuric acid are mixed together. The reaction is exothermic and the temperatures can reach 150 °C. The materials used here must therefore be able to resist hot concentrated sulfuric acid as well as hydrofluoric acid and possess adequate erosion resistance to fluorspar and calcium sulfate crystals. Depending on concentration and temperature, the materials alloy 20 (EN 2.4660/UNS N08020), alloy C-276 (EN 2.4819/UNS N10276), and alloy 59 (EN 2.4605/UNS N06059) are successfully used for these equipment items.

The second stage is a rotary kiln, in which the reaction is taken to completion. Some kilns, or their linings, are made of alloy 20 (EN 2.4660/UNS N08020), while in others, special stainless steels are used. Recently, good experience has been achieved with alloy 59 (EN 2.4605/UNS N06059) as a material for the rotary kiln. The gaseous hydrogen fluoride leaving the kiln is contaminated with entrained sulfuric acid and silicon tetrafluoride; these contaminants are removed in a sulfuric acid scrubber. The material for

the scrubber will be determined by the concentration of sulfuric acid in the scrubber liquid. In some plants, the high-alloyed stainless steel alloy 926 (EN 1.4529/UNS N08926) is successfully used; depending on the sulfuric acid concentration, alloy 31 (EN 1.4562/UNS N08031) or alloy 59 (EN 2.4605/UNS N 06059) may also be considered.

The HF gas is liquefied at ambient temperature in condensers made of carbon steel and then distilled in two stages to remove impurities. The volatile constituents are first removed in a carbon steel column. In the second stage, the less volatile impurities are removed. The residue is an aqueous mixture of hydrofluoric acid and sulfuric acid. In the upper part of the distillation column, carbon steel can be used, while alloy 400 (EN 2.4360/UNS N04400) is generally used for the lower part and the reboiler.<sup>39</sup>

Only a few special stainless steels and nickel alloys can be used for handling aqueous hydrofluoric acid solutions; alloy G-3 (EN 2.4619/UNS N06985), alloy 31 (EN 1.4562/UNS N08031), and alloy 59 (EN 2.4605/UNS N06059) are suitable within very narrow temperature and concentration limits.<sup>39</sup> If alloy 400 (EN 2.4360/UNS N04400) is used, it must be kept in mind that stress corrosion cracking can occur in air containing hydrofluoric acid vapors, and to a lesser extent also in the liquid phase.

Aluminum fluoride is produced in fluidized beds of aluminum oxide and hydrogen fluoride at a temperature of 650 °C. Owing to the excellent corrosion resistance of alloy 600 L (EN 2.4617/UNS N06600) at high temperatures in the presence of gaseous HF, this alloy is used to make the reactors and the tubes for the product coolers.<sup>39</sup>

### 3.05.5.6 Production of Acetic Acid

Acetic acid ( $\text{CH}_3\text{COOH}$ ) is the most important of the organic acids. It is used as a raw material in a large number of chemical processes. For example, acetic acid is used for the production of cellulose acetate, vinyl acetate monomer, acetic ester, pharmaceuticals, plastics, dyes, and insecticides. Acetic acid can be produced by fermentative oxidation of methanol. More common is the catalytic oxidation of hydrocarbons (e.g., butane) or the catalytic reaction of methanol and carbon monoxide:  $\text{CH}_3\text{OH} + \text{CO} \rightarrow \text{CH}_3\text{COOH}$ .

The most well known process using this route was developed by Monsanto, the license now being held by BP Chemicals. Rhodium activated with iodide acts as the catalyst. From carbon monoxide and the methyl groups, a complex compound is produced,

which is converted into acetic acid by hydrolysis, carbon dioxide and water arising as by-products. The exothermic reaction takes place at temperatures of 180–200 °C and a pressure of 15 bars in a special reactor. The acetic acid formed is then collected in an overhead condenser from where the iodine compounds are recycled to the reactor. The raw acetic acid is then distilled in two stages, with the unconverted methanol also being returned to the reactor.

The combination of hydroiodic acid, acetic acid, and water in the reactor, scrubber, and distillation columns produces extremely corrosive, reducing conditions. The materials in use for these items are alloy B-2 (EN 2.4617/UNS N10665), which is particularly corrosion resistant under reducing conditions, or alternatively zirconium.

After separation of the halogen ions, the acetic acid is less corrosive, so that the materials alloy C-276 (EN 2.4819/UNS N10276), alloy 59 (EN 2.4605/UNS N06059), alloy G-3 (EN 2.4619/UNS N06985), or alloy 31 (EN 1.4562/UNS N08031) can then be used in the downstream process equipment.

In other acetic acid processes like the Eastman process, in which no iodine is used, nickel–chromium–molybdenum alloys such as alloy C-276 (EN 2.4819/UNS N10276) and alloy 59 (EN 2.4605/UNS N06059) are likewise used.

### 3.05.5.7 Production of VCM

VCM is a feedstock for the manufacture of PVC and is nowadays produced from ethylene and chlorine. Ethylene is either converted directly with chlorine to form ethylene dichloride (EDC), which is then thermally cracked to produce VCM or ethylene is subjected to oxychlorination followed by pyrolysis.

As would be expected in pyrolysis processes, many equipment items are exposed to high temperatures and severe corrosive attack. The highly corrosive nature of dissolved chlorine and hydrogen chloride comes to the fore at elevated temperatures and, to a particularly strong extent, in the presence of moisture. Priority therefore attaches to the operation of a dry process. Any introduction of moisture or water would lead to the formation of hydrochloric acid and other corrosive media. As the demand for absolute dryness cannot be fulfilled in actual practice (start-up and shutdown, downtimes, leaks, decoking with steam), suitable measures must be found to prevent premature material failure as a result of corrosion. Where the process temperature permits, such measures include coatings (in most cases organic-based)

and the use of corrosion-resistant materials. According to Alves *et al.*,<sup>39</sup> here it is mainly nickel alloys that have proved successful in the relevant operating conditions. Thus, alloy 825 (EN 2.4858/UNS N08825) is used for gas inlet tubes and alloy 59 (EN 2.4605/UNS N06059) or alloy C-276 (EN 2.4819/UNS N10276) for tube sheets and as cladding material in the catalysis section of fluidized bed reactors. The fixed-bed reactors are equipped with vertical tubes that are usually made of the nickel standard grade alloy 200 (EN 2.4066/UNS N02200), alloy 600 (EN 2.4816/UNS N06600), or alloy 625 (EN 2.4856/UNS N06625).

Thermal cracking of the EDC to form VCM and hydrochloric acid takes place in a pyrolysis kiln at 425–550 °C. Alloy 800 H (EN 1.4958/UNS N08810) is the standard material for this application. A few facilities are also constructed in alloy 600 (EN 2.4816/UNS N06600). In the EDC purification section, the main corrosion problem is created by hydrochloric acid. Here, various nickel materials such as alloy 400 (EN 2.4360/UNS N04400), alloy B-2 (EN 2.4617/UNS N10665), and 6Mo stainless steels such as alloy 926 (EN 1.4529/UNS N08926) are used for columns, heat exchangers, pumps, and valves. The use of standard chromium–nickel steel grades cannot be recommended owing to their high susceptibility to pitting corrosion and stress-corrosion cracking in the special conditions of VCM production.

A characteristic feature of some older VCM plants is the flare stack used to burn off waste gases. Alloy 59 (EN 2.4605/UNS N06059) is suitable for the stack head, which is subject to heavy corrosive attack. For environmental reasons, in new facilities, this gas is no longer burnt off but recycled to the process. The same materials can be used for the recycling process as for the VCM process itself, because their corrosion behavior has to meet similar requirements.

### 3.05.5.8 Production of Styrene

Styrene ( $C_6H_5CH:CH_2$ ) is an important chemical for the production of a range of plastics, including polystyrene, SBR, ABS, and SAN resins, synthetic latexes, and polyesters. The main process used to produce styrene is the production of ethylbenzene in a first step by catalytic reaction of benzene and ethylene followed by the dehydrogenation of ethylbenzene.

In the first reaction stage, in which the ethylbenzene is produced, it is the corrosiveness of the catalyst that determines the type of material required. The Union Carbide/Badger process employs aluminum chloride as catalyst. Aluminum chloride is extremely

corrosive, meaning that only acid-resistant glass or ceramic linings come into consideration here. For metal linings, heating coils, and other internals, alloy B-2 (EN 2.4617/UNS N10665) and alloy C-276 (EN 2.4819/UNS N10276) can be used. The same alloys are also used in the downstream heat exchangers and piping systems. Columns and heat exchangers that come into contact with traces of chlorides are often made of the nickel–copper alloy 400 (EN 2.4360/UNS N04400). Special stainless steels such as the 6Mo grade alloy 926 (EN 1.4529/UNS N08926) can also be considered.

Other ethylbenzene processes use noncorrosive catalysts, and therefore, only low-alloy materials are required in the first stage.

The second process stage, in which hydrogen is split off, runs at high temperatures (950–1000 °C) in the presence of superheated steam. The steam is produced in furnaces in which the tubes and the manifolds are generally made of alloy 800 H (EN 1.4958/UNS N08810). The connection line from the superheater to the reactor may also be made of the same material. High temperature materials are also used for the reactor in which dehydrogenation takes place. These are mainly heat-resistant steels such as alloy 800 H (EN 1.4958/UNS N08810) or nickel alloys such as alloy 617 (EN 2.4663/UNS N06617). The exact choice of material depends on the design and the degree of attack.

### 3.05.5.9 Production of Acrylic Acid and Acrylate Esters

Acrylic acid ( $\text{C}_2\text{H}_3\text{COOH}$ ) is a feedstock for the production of polyacrylic acid and acrylic esters. Acrylate esters (such as methyl acrylate, ethyl acrylate, butyl acrylate, etc.) are used in polymerized form for the production of dyes and paints, adhesives, textiles, and plastics. Polyacrylic acid is used in the production of hygiene products, cleaning products, and water treatment agents.

The most important process for the production of acrylic acid is the partial oxidation of propylene. In general, this process is regarded as ‘noncorrosive,’ enabling low-alloy steels to be used. Recently, however, a number of cases of corrosion damage have occurred in the extraction column. These problems have been attributed to traces of formic acid in the plant. Field tests have led to the selection of different materials according to the corrosiveness of the medium. Thus, in one plant, the 6Mo stainless steel grade alloy 926 (EN 1.4529/UNS N08926) was selected, in another plant

the nickel alloy C-276 (EN 2.4819/UNS N10276), and in a third plant alloy 31 (EN 1.4562/UNS N08031).

Acrylate esters are produced by reacting acrylic acid with the corresponding alcohol in the presence of a catalyst. The catalyst can, for example, be sulfuric acid or sulfonic acid; the reaction temperature is in the order of 130 °C. An oxidizing or reducing stabilizer is added to prevent polymerization. The corrosiveness of the process is determined by the type of catalyst. Therefore, the choice of material for the reactor, heating tubes, and mixer will be determined by its corrosion resistance to sulfuric or sulfonic acids under either oxidizing or reducing conditions.

When reducing conditions are encountered, the copper–nickel alloy 400 (EN 2.4360/UNS N04400) can be successfully employed. It should be kept in mind, however, that alloy 400 loses its resistance to corrosion under oxidizing conditions. In one plant, severe corrosive attack was observed when the stabilizer was converted from reducing to oxidizing. Extensive exposure tests as much with high-alloy stainless steel grades as with the nickel alloy grades alloy G-3 (EN 2.4619/UNS N06985), alloy 625 (EN 2.4856/UNS N06625), alloy 31 (EN 1.4562/UNS N08031), alloy C-276 (EN 2.4819/UNS N10276), alloy 59 (EN 2.4605/UNS N06059), etc. showed that alloy 59 was the only material exhibiting an overall corrosion rate below  $0.01 \text{ mm year}^{-1}$  and no pitting or crevice corrosion. For this reason, alloy 59 (EN 2.4605/UNS N06059) was selected for the particularly critical part of the plant, the heating tubes. As Alves *et al.*<sup>39</sup> report, after 3 years in use without any problems, the entire reactor was constructed in alloy 59.

### 3.05.5.10 Production of MDI and TDI as Feedstocks for Polyurethanes

Polyurethanes are produced by the polyaddition of isocyanates and alcohol. The most common processes use MDI and TDI as feedstocks. MDI and TDI are synthesized by conversion of diamines in the presence of carbonyl chloride (phosgene).

In the synthesis of both MDI and TDI, hydrogen chloride is generated as a by-product. Owing to the corrosiveness of HCl it is generally necessary to use corrosion-resistant materials. The heat exchangers downstream of the reactor are exposed to corrosive attack from a mixture of TDI, HCl, and phosgene (in traces) at temperatures of  $\sim 200^\circ\text{C}$ . The nickel–chromium alloy 600 L (EN 2.4817/UNS N06600) is generally used for these heat exchangers. Under normal conditions, this material lasts  $\sim 10$  years. Under

particularly critical conditions, alloy 59 (EN 2.4605/UNS N06059) has been successfully selected.

In other areas of the plant, materials are required that are resistant to hydrochloric acid in aqueous solution. Depending on the overall process, the process stage and the precise composition of the medium, the nickel alloy grades alloy B-2 (EN 2.4617/UNS N10665), alloy 400 (EN 2.4360/UNS N04400), alloy C-276 (EN 2.4819/UNS N10276), or alloy 59 (EN 2.4605/UNS N06059) are used.<sup>39</sup>

Recently, a new gas phase technology has emerged whereby alloy C-4 and alloy 59 have proved to withstand corrosion in key equipment parts. In the reactor sump vessel, the mixture of TDI, hydrogen chloride, and phosgene at high temperature leads to strong pitting on standard stainless steel. In field tests and long-term pilot plant operation, alloy C-4 (EN 2.4610/UNS N06455) and alloy 59 (EN 2.4605/UNS N06059) have proved to be the material of choice.

### 3.05.5.11 Production of Fine and Specialty Chemicals

The fine and specialty chemicals industry produces a wide variety of chemical ingredients and active intermediates to be used, for example, in the pharmaceutical, food, agrochemical, and home and care industries. The selection of materials for the production of fine chemicals is made more difficult by the fact that the chemical plants involved are increasingly used to produce different types of substances to satisfy fast-changing market demands, so that reactors, vessels, piping systems, and heat exchangers are frequently exposed to changing corrosive media requiring the use of equally versatile multipurpose materials.

In addition, metallic contamination of the final product is not tolerable in many cases. Dissolved metallic ions may either lead to a discoloration of the products or trigger undesired catalytic reactions within the products or their amount may be limited by legal requirements. For this reason, specifications have to be met in many cases where tolerable mass loss is far below the corrosion rate of  $\leq 0.1 \text{ mm year}^{-1}$ , which is usually considered the limit for the technical corrosion resistance in case of metallic alloys.<sup>54</sup> The requirement for resistance to a broad spectrum of different media, which is given in most cases leads to the selection of either nonmetallic materials, like glass-linings and polymers, or special metallic materials. Such special metallic materials are alloys belonging to the family of C-type nickel–chromium–molybdenum alloys, titanium, zirconium, and

tantalum. Lower-alloyed materials like alloy 31 (EN 1.4562/UNS N08031) are useful to a certain extent.

C-type nickel–chromium–molybdenum alloys, particularly alloy 59 (EN 2.4605/UNS N06059) can be considered for critical equipment as synthesis reactors and distillation columns. In the case of centrifuges, fittings, agitators, and valves, the material selection is mainly restricted to metals due to mechanical and design requirements.

Furthermore, cleanability is an important issue in multipurpose plants. In the case of nickel alloys, a high degree of cleanability can be achieved by electropolishing. Electropolishing of nickel alloys allows obtaining extremely smooth surface structures to which it is difficult for the products to adhere. In addition, the true surface area of an extremely smooth surface is considerably reduced compared with a surface of greater roughness, which results in a lower corrosion rate of the alloy and less migration of alloying constituents to the product. However, obtaining smooth surfaces by electropolishing requires a high degree of homogeneity of the alloy that has to be part of the material specification for this reason.

The wide variety of service media encountered in this industry is outside the scope of this work. As an example, reactions involving organic acid or solvents and catalyzed by small amounts mineral acids like sulfuric acid or hydrochloric acid can be found in the production of fine chemicals. Although more corrosive than the sulfuric acid, the hydrochloric acid is sometimes preferred owing to its higher catalytic activity. Oxidizing contaminants like oxygen, ferric, or cupric ions should also be considered, because they tend to shift the redox potential.

Figures 25 and 26 present data from laboratory tests intended to simulate in a simplified manner such type of environments.<sup>55</sup> Distinct levels of dissolved oxygen were achieved by bubbling nitrogen or oxygen into the solution and different concentrations of ferric ions were added in the form of sulfate. As indicated by the results, alloy 31 (EN 1.4562/UNS N08031) may sometimes require a shift of the free corrosion potential to more oxidizing conditions in order to make it corrosion resistant in these media. Alloy 59 (EN 2.4605/UNS N06059), however, exhibits very low corrosion rates under all conditions tested. Nickel–molybdenum alloys of the B-type are not considered for changing conditions in multipurpose plants, as they are resistant to few specific media only. In addition, their corrosion rate is increasing strongly with increasing amounts of accompanying oxidizing substances.

**Figure 25** Corrosion behavior of alloy 31 (EN 1.4562/UNS N08031), alloy 59 (EN 2.4605/UNS N06059), and alloy B-2 (EN 2.4617/UNS N10665) in 50% CH<sub>3</sub>COOH + 40% HCOOH + 5% H<sub>2</sub>SO<sub>4</sub> + 5% H<sub>2</sub>O under different oxidizing conditions at 95 °C, graph made from data (Table 3 in Alves and Werner<sup>55</sup>) determined by Alves *et al.* in a 24 h immersion tests.

**Figure 26** Dependence of corrosion rate on the free corrosion potential of alloy 31 (EN 1.4562/UNS N08031) and alloy 59 (EN 2.4605/UNS N06059) in 94% C<sub>2</sub>H<sub>5</sub>OH + 2% HCl + 4% H<sub>2</sub>O at 60 °C, determined by Alves *et al.* in a 24 h immersion tests. Reproduced from Alves, H.; Werner, H. *CORROSION* 2004; NACE International: Houston, TX, 2004, Paper No. 04235.

An additional study by Alves *et al.*<sup>56</sup> on the corrosion resistance in organic solvents with small amounts of sulfuric acid or hydrochloric acid showed again that alloy 31 (EN 1.4562/UNS N08031) requires a threshold oxidizing capacity to passivate, being preferred for the more oxidizing conditions. Alloy 59 (EN 2.4605/UNS N06059), however, revealed to be the more versatile alloy, having good resistance in the most environments studied. Alloy 59 (EN 2.4605/UNS N06059) shows higher ability to

passivate and little susceptibility to variations on the content of oxidants or chlorides. Another interesting conclusion of the same study is that the corrosive impact of the small additions of HCl (2%) depends on the solvent and decreases in the sequence: methanolic solution > ethanolic solution > aqueous solution as a result of the different protonic activity. If methanol is used as a solvent, a certain threshold of water is required to maintain the passivity of nickel alloys. The water contents required to maintain

passivity and the corrosion rate  $<0.1 \text{ mm year}^{-1}$  were found to be 8% at 40 and 50 °C for the unwelded alloy 31 (EN 1.4562/UNS N08031), and 12% at 40 °C and 18% at 50 °C for the welded alloy 31. Alloy 59 (EN 2.4605/UNS N06059) requires significantly lower amounts of water to maintain passivity (2% at 40 °C and 4% at 50 °C) and is not influenced by the welding conditions.

The C-type family of nickel–chromium–molybdenum alloys, in particular, alloy 59 (EN 2.4605/UNS N06059), offers a high level of reliability when equipment items are exposed to a variety of corrosive media. Indeed, this versatile alloy is suitable for a wide variety of corrosive environments, including mineral and organic acids, acid mixtures, halides, etc., and resists high levels of chlorides, oxidizing and reducing contaminants, and stress-corrosion cracking. Thus, alloy 59 (EN 2.4605/UNS N06059) can often be considered to replace more expensive materials like zirconium and tantalum or the mechanically fragile enamel.

### 3.05.5.12 Transport of Corrosive Dangerous Goods in Tanks

In Germany, the “BAM – List Requirements for Tanks for the Transport of Dangerous Goods” with compatibility evaluations of selected metallic material groups as well as of polymeric gasket and lining materials under the influence of dangerous goods and water-polluting substances is the basis for substance-related prototype approvals for tank containers designed for the carriage of dangerous goods.<sup>57</sup> Such information is applicable also to tanks, trucks, and rail cars. There are a large number of dangerous goods with high corrosivity to metals where the standard steels are not corrosion resistant. One possibility to solve corrosion problems is to line the tank with a polymeric material. An alternative possibility is the application of high-alloyed stainless steels and nickel alloys as there are alloy 31 (EN 1.4562/UNS N08031) and alloy 59 (EN 2.4605/UNS N06059). For lack of corrosion test results with welded test samples of these high-alloyed materials under the influence of corrosive dangerous goods, a comprehensive test program was performed in 14 relevant groups of media at 55 °C.<sup>58,59</sup>

The results obtained indicate that alloy 59 (EN 2.4605/UNS N06059) showed the most universal corrosion resistance of the materials tested. This alloy is suitable as material for tanks transporting almost all corrosive substances having been included in the test series. One exception is the limitation of temperature during the transport of hydrochloric acid.

Alloy 31 (EN 1.4562/UNS N08031) is very corrosion resistant, but more restricted in its use than alloy 59. Exceptions for the use of this material are hydrochloric acid, perchloric acid, and molten monochloroacetic acid at 110 °C. Limitations for the use exist in the concentration range of aqueous solutions of aluminum chloride, copper (II) chloride, ferric chloride, and 2-chloropropionic acid. Alloy 31 can be considered corrosion-resistant tank material for the transport of mixtures of concentrated nitric acid and 96% sulfuric acid if the content of the nitric acid does not exceed 50% or the temperature does not exceed 30 °C. Alloy 31 has excellent prospects for application in transportation tanks because of the multipurpose corrosion resistance characteristics in combination with the beneficial cost ratio in comparison with the standard stainless steel grade AISI 316L.

All details of those and future test results will be included in the most recent edition of the BAM-List – Requirements for Tanks for the Transport of Dangerous Goods.

### 3.05.5.13 Environmental Technology

Air pollution control occupies a leading position in the market for environmental technology. Therefore, the subject of this section<sup>16</sup> is the removal of oxidation products of the sulfur and of the accompanying HCl/HF gases from the combustion processes of organic materials (coal, lignite, oil) by chemical gas scrubbing. This process is generally known as ‘FGD’ and the associated plants as ‘FGD plants.’

The wide range of scrubbing processes developed can be divided into scrubbing processes with regeneration of the scrubbing solution, spray absorption processes, and scrubbing processes without regeneration of the scrubbing solution. The scrubbing processes without regeneration, the so-called limestone processes are used throughout the world in ~90% of all FGD plants.

In a typical single-circuit process limestone FGD plant, the flue gas passes through an electrostatic precipitator; subsequently, the dust-free raw gas is sprayed with a scrubbing suspension in a quencher, whereby it is cooled and saturated with water vapor. In plants with a heat recovery system, the raw gas is cooled from ~200 to 300 °C (with/without NO<sub>x</sub> reduction) to 150 °C by means of a so-called clean gas preheater before entering the scrubber. The gas flow and the circulation of the scrubbing suspension are adjusted so that the temperature of the scrubbing suspension is ~60 °C. The pH is adjusted to between

4.5 and 6. In the scrubber sulfur dioxide/sulfur trioxide ( $\text{SO}_2/\text{SO}_3$ ) are transformed by the addition of limestone into calcium sulfite ( $\text{CaSO}_3$ ) and subsequently transformed by the injection of air or oxygen into essentially insoluble  $\text{CaSO}_4 \times 2 \text{H}_2\text{O}$ , that is, gypsum. This essentially insoluble gypsum precipitates out, and thus promotes the very high  $\text{SO}_2/\text{SO}_3$  conversion rate of over 90%. A suspension of quicklime ( $\text{CaO}$ ), hydrated lime ( $\text{Ca(OH)}_2$ ), or limestone ( $\text{CaCO}_3$ ) is used as the scrubbing solution. Chemical buffer reactions provide a constant pH in the absorber after the start-up phase of a FGD plant. Secondary reactions that take place after entry into the quencher or the bottom section of the integrated absorber are the almost 100% removal of hydrogen chloride ( $\text{HCl}$ ) and hydrogen fluoride ( $\text{HF}$ ), which are produced in the combustion process by chemical reactions and carried over with the flue gas. In counter-current systems, the flue gas is again sprayed with the scrubbing suspension in the upper region of the scrubber, the limestone excess in the added suspension resulting in a further increase in the degree of desulphurization. A pH shift toward a pH of  $\sim 6$  is obtained by the buffer reaction of hydrogen carbonate. The main reaction in the FGD therefore consists in the transformation of sulfur oxides into inert insoluble end products (gypsum) in a weakly acidic medium. The resultant attack of the material arising from this process is in principle not critical. Practice shows, however, that particular zones within the plant are more sensitive with regard to materials than others, apparently because of secondary reactions or nonequilibrium conditions. Effects such as local temperature variations, catalytically acting surface conditions, and the tendency toward formations of incrustations and concentrations of individual harmful ions contribute to this. This results in zones ranking in their aggressiveness from slight to very severe requiring a whole spectrum of corrosion-resistant materials, from high-alloy stainless steels to nickel alloys.

The lower-alloyed stainless steels can – as a simplification – only be used in the area of the FGD absorber in very mild conditions, at low temperatures and if the development of concentrations under incrustations or deposits can definitely be ruled out, that is to say, in the neutral to weakly acidic region, if the chloride ion concentration is adjusted to  $\leq 0.5\%$ . The operating range of the alloys mentioned in [Table 1](#), for example, alloy 31 (EN 1.4562/UNS N08031) commences in weakly acidic solutions and extends to strongly acidic solutions with moderate chloride ion attack. Higher-alloyed nickel alloys are

usually used at chloride concentrations  $>0.5\%$  and in acidic to very strongly acidic conditions as well as where temperature increases to well over  $70^\circ\text{C}$  are expected. At temperatures over  $100^\circ\text{C}$ , with large fractions of chloride in the flue gas and much incrustation with dust or gypsum deposits, only the highest-alloyed materials such as alloy C-276 (EN 2.4819/UNS N10276) and alloy 59 (EN 2.4605/UNS N06059) turned out to have long-term resistance, but even these two broadly similar materials in practice exhibited marked differences in resistance to the most aggressive FGD conditions. In the past, countless reference plants have shown that alloy 59 (EN 2.4605/UNS N06059) is the only material that is still in use in an undamaged condition, even after many years of operation, in areas that are at greatest risk of corrosion such as the raw gas inlet of an FGD plant in a lignite-fired power station, and can also guarantee safe operation of the plant for its entire service life.

With this simplified representation of the areas of application of the special steels and nickel alloys, it is, however, vital to bear in mind that the actual material specification is only possible with reference to the specific project and by the material manufacturer, the equipment fabricator, the engineering consultant, and the plant operator working together. In doing so, a large number of other parameters such as processing, fuels, mode of plant operation, operating temperatures, magnitude, and frequency of deviations from the state of equilibrium, proportion of particulates, incrustations, design, and geometry of the components have to be taken into account.

It is economically sensible to produce in metal all the components of the heat recovery system, the quencher with the raw gas inlet, the absorber, the ducting, the second heat exchanger, and the stack. Nickel alloys are to be used for the components that will be subjected to the most aggressive media. Heat recovery systems, raw gas inlet areas, as well as fixing and sealing elements of dampers, are as a rule the components that are usually subjected to high condensate attack, and must therefore be made from the most-resistant materials. In recent years, alloy 59 (EN 2.4605/UNS N06059) has been used to a large extent for this application. Alloy C-276 (EN 2.4819/UNS N10276) may also be selected for these components; however, with this, the reserve capacity of alloy 59 is not quite attained. Since failure of fastening components could be disastrous and because of the extreme crevice conditions encountered there, alloy 59 (EN 2.4605/UNS N06059) is recommended for any fastening components too.

Alloy 59 is also recommended as a universal filler metal in welding, taking advantage of its high corrosion resistance combined with its high thermal stability.

If a stable chemical system with pH values in the range 4.5–6.5 is formed in the absorber sump and thus the aggressiveness can be calculated, and also as long as the chloride content is not too high, even alloy 31 (EN 1.4562/UNS N08031) can be used, given an exact knowledge of the operating conditions. The condition for the use of the latter material, however, is the avoidance of gypsum deposits by designing the agitating units accordingly. If there are any doubts, it is better to manufacture the absorber sump region in alloy 59 (EN 2.4065/UNS 06059), for example, in clad form (10 + 4 mm). In the transition zone from the raw gas inlet to the wet–dry interface of the sump, certain areas have to be constructed with a greater amount of alloy 59 or alloy C-276.

This also applies to the quencher nozzle system up to the process-specific transition into the absorber region (bowl in the dual-circuit scrubber). The first absorption planes, that is, the first spray pipe layers above the quencher nozzle system, can be made from alloy 31 (EN 1.4562/UNS N08031). The head of a dual-circuit absorber may be made from a high-alloy stainless steel, depending on the effectiveness of the mist eliminator. The heat recovery system, which is coupled with the raw gas inlet must, even in the parts where the gas is clean, be fabricated from nickel alloys of the type alloy 59 (EN 2.4605/UNS N06059).

It is necessary to make a distinction between coal-fired and lignite-fired power stations where the clean-gas connections to the stack are concerned. While, as a rule, in lignite-fired power stations with heat recovery systems, very clean treated gas duct conditions usually occur and thus limited deposits form, the situation in coal-fired power stations is the opposite. In particular, if there is no heat recovery system and the mist eliminator system is not working effectively or is not rinsed out frequently, thick deposits form in coal-fired power stations, which can give rise to an extremely high risk of corrosion with simultaneous condensate formation, particularly in the 6 o'clock position and in the flow deviation areas, and at design-related flow interruption points. Clean-operating treated gas ducts can, in some cases, even be fabricated from alloy 31 (EN 1.4562/UNS N08031) or even from a 6Mo stainless steel such as alloy 926 (EN 1.4529/UNS N08926). With all other methods of operation, higher-alloyed nickel alloys must be used, particularly in the 6 o'clock position and at the other flow interruption points, to achieve a

corresponding increase in corrosion resistance. Stack inlet pipes or stacks built of solid metal usually require the materials alloy C-276 (EN 2.4819/UNS N10276) and alloy 59 (EN 2.4605/UNS N06059), since it is not possible to calculate accurately over the stack height and cross-section where the condensation zone occurs as a function of the external climate. Massive damages to coating systems (resin coatings with flake filling) as well as serious rotting of unprotected concrete stacks have recently increased the use of metallic nickel–chromium–molybdenum materials in stack construction.

Despite some fluid mechanics-related requirements, materials for shut-off fittings, for example, dampers and gates, must naturally be assessed according to their location in the gas stream. The material selection is obviously based on the aforementioned remarks.

On the basis of past experience, the selection of suitable materials specific to the component can guarantee a better long-term reliability and thus higher plant availability. If costs dictate thin-walled application of highly corrosion-resistant materials, this can be produced by the cladding of existing or new carbon steel structures with thin large sheets of nickel–chromium–molybdenum materials (wallpapering), or by the use of explosively or roll-bond clad composites with highly corrosion-resistant cladding materials.

$E_{\text{corr}}$  Corrosion potential  
 $i_{\text{corr}}$  Corrosion current density

## 3.06.1 Metallurgy

### 3.06.1.1 Introduction

Cobalt is one of the transition metals appearing between iron and nickel; it was discovered by Brandt in 1735. Depending on temperature, there are two allotropic modifications of cobalt: face centered cubic (fcc), which is stable above 690 K and hexagonal close packed (hcp), stable below 690 K. Pure cobalt is soft and it has poorer oxidation resistance than nickel and iron. However, the alloying of cobalt with chromium and various quantities of carbon and tungsten results in the family of Stellite alloys, which have excellent corrosion and wear resistance. Cobalt is generally obtained as a secondary product from the mining of other elements, particularly copper and

nickel; relatively minor quantities (15%) derive from primary cobalt mining.<sup>1</sup> Current production is around ~50 000 tonnes per annum at a producer cost generally from three to five times that of nickel.

The cobalt-base alloys are extremely resistant to many forms of wear and moderately resistant to many forms of corrosion. For example, alloys optimized for wear resistance generally include significant carbon addition, which results in the formation of carbides in the microstructure during alloy solidification. These carbides increase the hardness of the alloys and their resistance to low-stress abrasion. Key applications are in wear and erosion-resistant alloys (e.g., the Stellite family and cemented carbides) and in high temperature oxidation-resistant alloys: these comprise ~40% of cobalt use. The balance of production is used in batteries (25%), magnetic alloys (6%), colors and pigments (10%), catalysts (9%), etc.

Alloys designed for service in severely corrosive environments typically contain low carbon levels. Not only does this markedly improve resistance to corrosion, but also it increases ductility. The chief benefits of high carbon content are increased hardness and enhanced resistance to low-stress abrasion, both of which increase with increasing carbon content. Aspects of the corrosion resistance are discussed in detail later in the chapter.

In forming carbides, the carbon ties up a portion of vital alloying elements, such as chromium. The effective chromium content from a corrosion standpoint (the chromium remaining in the solid solution) is therefore considerably lower than indicated by the nominal composition. Carbide forming elements such as tungsten (which forms  $W_6C$  type carbides) may reduce the amount of carbon required to reach the eutectic composition.

### 3.06.1.2 Alloying

Historically, many of the commercial cobalt-base alloys are derived from the cobalt–chromium–tungsten and cobalt–chromium–molybdenum ternaries first investigated by Elwood Haynes in the beginning of the twentieth century.<sup>2</sup> He discovered the high strength and stainless nature of the binary cobalt–chromium alloy, and he later identified tungsten and molybdenum as powerful strengthening agents within the cobalt–chromium system. When he discovered these alloys, Haynes named them the Stellite alloys after the Latin ‘stella’ (star), because of their star-like microstructure. Having discovered their high strength at elevated temperatures, Haynes also promoted the use of Stellite alloys as cutting tool materials. In [Figure 1](#) a typical microstructure of the Stellite 6 alloy is shown and the

**Figure 1** Typical microstructure of Stellite 6 alloy: (a) analysis area composition in wt% is 60.8% Co, 29.8% Cr, 6.2% W, 1.7% C, 1.4% Fe (b) is eutectic Cr-rich carbide, and (c) is the Co rich matrix. Reproduced from Malayoglu, U. PhD Thesis, Heriot-Watt University, 2005.<sup>3</sup>

complex structure of eutectic carbides and the Co-rich matrix is clear.

The chemical constitution of cobalt alloys is analogous to the general family of stainless steels and the role of major and minor alloying elements is virtually identical throughout these austenitic alloy systems. The addition of alloying elements alters the thermodynamic stability of the fcc compared with the hcp phases by either enlarging or constricting their fields. These alloys also effect the martensitic transformation by influencing the  $M_s$  (martensitic start) and  $A_s$  (austenite start) temperatures.

In cobalt-base alloys, the key element, chromium, is added in the range of 20–30 wt% to improve corrosion and wear resistance and for some measure of solid-solution strengthening. Where carbide precipitation strengthening is a desirable feature, chromium also plays a strong role through the formation of a series of varying chromium-carbon ratio carbides such as  $M_7C_3$  and  $M_{23}C_6$ .  $M_7C_3$  carbides, which have a hexagonal crystal structure and contain ~70 wt% Cr, ~12 wt% Co, and small amounts of other metallic elements in the alloy.

The refractory elements, tungsten and molybdenum, are utilized as the major solid-solution strengtheners for both wrought and cast cobalt alloys, while those of lower solubility such as tantalum, columbium, zirconium, and hafnium are generally more effective in their carbide forming role. Molybdenum and tungsten produce strengthening by formation of intermetallic compounds of  $Co_3M$  and MC carbides and the formation of  $M_6C$  carbides

For cast alloys, Morrow *et al.*<sup>4</sup> demonstrated that replacing tungsten with an atomic equivalent addition of molybdenum improves elevated tensile and rupture ductility without decreasing strength in alloys such as FSX 414 and MM 509. Additionally, alloy cost and density decreases with little change in expansion coefficient or microstructural characteristics. However, molybdenum addition slightly decreases the solidus and liquidus temperatures and increases the total solidification range, which somewhat alters the carbide morphology and produces additional eutectic carbides.

The refractory element rhenium has been successfully utilized in nickel alloys for solid solution strengthening; however, its potential in cobalt alloys has not fully been explored. Like tungsten, it exhibits extensive solubility in the matrix and increases the solidus and liquidus temperatures. Of the alloying elements, tungsten produces a favorable increase in melting temperature. Tantalum has been successfully utilized as a replacement for tungsten in high temperature sheet alloys MM-918 and S-57, where

**Table 1** The effect of several elements in cobalt-base superalloys

<i>Element</i>	<i>Effect</i>
Chromium	Improves oxidation and hot-corrosion resistance; produces strengthening by formation of $M_7C_3$ and $M_{23}C_6$ carbides
Molybdenum	Solid-solution strengtheners; produce strengthening by formation of intermetallic compound $Co_3M$ ; formation of $M_6C$ carbide
Tungsten	Solid-solution strengtheners; produce strengthening by formation of intermetallic compound $Co_3M$ and MC carbide; formation of $M_6C$ carbide
Tantalum	
Columbium	Improves oxidation resistance; formation of intermetallic compound CoAl
Aluminum	
Titanium	Produces strengthening by formation of MC carbide and intermetallic compound $Co_3Ti$ ; with sufficient nickel produces strengthening by formation of intermetallic compound $Ni_3Ti$
Nickel	Stabilizes fcc form of matrix; produces strengthening by formation of intermetallic compound $Ni_3Ti$ ; improves forgeability
Boron	Produce strengthening by effect on grain boundaries and by precipitate formation; zirconium produces strengthening by formation of MC carbide
Zirconium	Produces strengthening by formation of carbides MC, $M_7C_3$ , $M_{23}C_6$ , and possibly $M_6C$
Carbon	
Yttrium	Increases oxidation resistance
Lanthanum

some improvement in oxidation resistance was also demonstrated. The effect of different alloying elements is summarized in [Table 1](#).

### 3.06.1.3 Microstructure and Microstructural Influences

The microstructure of Stellite alloys varies considerably with composition. They may either be in the form of hypoeutectic structure consisting of primary dendrites of a cobalt-rich solid solution surrounded by eutectic carbides, or of hypereutectic type containing large idiomorphic primary chromium rich carbides and eutectic.

Among the alloying elements, carbon is found to have a large influence on the microstructure, causing a change from a hypoeutectic to hypereutectic alloy. [Figure 2](#) shows the phase diagram for the

**Figure 2** Cobalt-carbon binary system. Reproduced from Atamert, S. Stability, wear resistance and microstructure of iron, cobalt and nickel-based hardfacing alloys, PhD thesis, University of Cambridge UK, 1989.<sup>5</sup>

carbon-cobalt alloy system. As can be seen in the hypoeutectic side of the system (<1.6at% of C) the liquidus temperature of the alloy decreases by  $\sim 14^\circ\text{C}$  for each 1% increase in carbon content. Carbon is clearly critical to those casting alloys formulated for the highest creep rupture strength levels, since carbide strengthening is the primary precipitation hardening mechanism utilized in the cobalt alloy system. The control of carbon is critical for tensile and rupture strength and ductility since it has been shown that a nonlinear increase in strength occurs over a range of  $\sim 0.3\text{--}0.6\%$  carbon.

The strength of most cobalt base superalloys is derived from the carbide phases present in the matrix and distributed around the grain boundaries. The carbides that form depend on the composition and thermal history of the material. The carbide former elements are from group IV (Ti, Zr, Hf), group V (Cb, Ta), and group VI (Cr, Mo, W). The types of carbides that are formed are as follows (M and C represents metal and carbon atoms respectively):

$\text{M}_3\text{C}_2$ : rhombic, a high chromium content carbide which forms at low Cr/C ratio;

$\text{M}_7\text{C}_3$ : trigonal, a high chromium content carbide which forms at a slightly higher Cr/C ratio;

$\text{M}_{23}\text{C}_6$ : cubic, a high chromium content carbide which forms at an higher Cr/C ratio, when the Cr is greater than 5 wt% of the alloy;

$\text{M}_6\text{C}$ : complex cubic, a carbide phase whose volume fraction increases as refractory metals are introduced;

MC: fcc NaCl structure, a carbide comprising metal groups IV and VI.

These carbides are listed above in the order of increasing stability, or free energy of formation. The stronger the carbide formers used, the greater is the tendency to form  $\text{M}_6\text{C}$  and MC carbides. The type of carbides that form is dependent upon both thermal history and composition. Lane and Grant<sup>6</sup> suggested a transformation of  $\text{M}_7\text{C}_3\text{--M}_{23}\text{C}_6$  during aging in an X-40 casting, which is described by the reaction

This demonstrates that a nonequilibrium structure exists in Co castings at high temperatures.

The microstructure of cobalt base superalloys is thus a combination of MC,  $\text{M}_7\text{C}_3$ ,  $\text{M}_{23}\text{C}_6$ , and  $\text{M}_6\text{C}$  carbides. In the cast structures, both composition and shape help to distinguish one carbide from another. The MC carbides have two characteristic shapes, a Chinese script and a block-like angular particles. The differences are believed to be the result of formation at various times during solidification. Block-like angular MC carbides may form initially before the bulk of the melt has started to solidify, whereas in the Chinese script, MC carbide is formed within the eutectic composition.<sup>7</sup>

$\text{M}_{23}\text{C}_6$  carbides are found mostly as fine plates interlayered with the cobalt matrix. This eutectic structure has a block-like shape. Subsequent heating of the cast structure can dissolve the  $\text{M}_{23}\text{C}_6$  carbides. Upon aging, the carbides are precipitated as fine particles, usually near the eutectic  $\text{M}_{23}\text{C}_6$  islands. In contrast to other carbides, the  $\text{M}_6\text{C}$  carbides do not have a characteristic morphology. Other important microstructural features of cobalt base superalloys are stacking faults, which have been reported to be present on all  $\{111\}$  planes.<sup>8</sup> Stacking faults appear to be related to the tendency to form hcp. Since stacking faults in fcc materials have an hcp structure, this is not surprising.

Many of the chemical attributes of the cobalt-based alloys derive from their crystallographic characteristics, which are summarized in Figure 3. The influence of alloying elements such as iron and nickel is explained through their effect on the stacking fault energy (SFE). Ni, Mn, and Fe have a strong effect on the SFE stabilizing the fcc allotrope, but Mo, W and Cr tend to stabilize the hcp allotrope and decrease the SFE. The excellent erosion resistance of cobalt-based

**Figure 3** Effect of alloying elements on the fcc-hcp transformation in cobalt as a function of solubility. Reproduced from Sims Chester, T.; Stoloff, N. S.; Hagel, W. C. *Super Alloys II*; John Wiley & Sons: London, 1987.<sup>9</sup>

Stellite alloy is greatly attributed to the low SFE, which in turn means higher stacking fault probability and a greater chance for the formation of  $\epsilon$  hcp platelets. The lower the SFE (the greater the width of stacking fault), the more difficult cross-slip is and the higher the work hardening and the strain to fracture. The materials with low SFE tend to strain harden rapidly, and show the highest galling resistance.

The effect of stacking faults may be detrimental to overall mechanical properties of cobalt base superalloys. Stacking faults have been shown to contribute to the strength of materials by inhibiting dislocation flow.<sup>5</sup> They also serve as sites for precipitation of second phases in cobalt base superalloys, which can likewise increase strength.<sup>10</sup> In contrast, it has been suggested that excessive stacking faults decrease the ductility of cobalt base superalloys to a value unacceptable for commercial use.

Stellite 6B is more likely to transform to hcp phase than most cobalt-base alloys since the fcc stabilizing elements iron and manganese are present in small amounts. Although carbon has a strong stabilizing effect in solution, most of it is tied as carbides. In fact, by suitable heat treatment, partial transformation may be achieved by thermal exposure alone.

Addition of iron and nickel are known to increase the stability of the fcc phase (and therefore, the SFE) of cobalt-base alloy. Furthermore, an increase in the SFE results in a change in the mode of deformation. The  $\alpha \rightarrow \epsilon$  transformation occurs to a lesser extent and there is a greater tendency towards slip of undissociated dislocations  $\{111\}$  phase. The  $\alpha \rightarrow \epsilon$  phase transformation and the formation of mechanical twins have

been found to cause rapid increase in the work hardening rate while also producing a maximum in the strain to fracture. These two phases are considered necessary for erosion resistance and therefore, any factor suppressing these structural changes must lead to a decrease in resistance.

### 3.06.1.4 Alloy Systems

The cobalt-chromium-carbon system is characterized by the affinity of chromium for the formation of carbides of various types in which cobalt can replace some of the chromium. Wever and Haschimoto<sup>11</sup> carried out extensive studies on the solidification behavior of cobalt-chromium-carbon alloys of various compositions by thermal analysis. According to their findings the 30% Cr, 1% C alloy has a solidification range (the temperature difference between the solidus and liquidus temperatures) of  $\sim 150^\circ\text{C}$ . In the carbon content range of 1.0% to 1.7%, the solidification range decreases by  $\sim 5.5^\circ\text{C}$  with each 0.1% increase in carbon content. Also, they showed that at 1% carbon, an increase in chromium from 20% to 30% results in reduction of the solidification range by  $\sim 50^\circ\text{C}$ .

Koster and Spencer<sup>12</sup> studied the constitution of the cobalt-chromium-tungsten alloy system and their work showed for up to  $\sim 30\%$  chromium and 15% tungsten the microstructure at room temperature consists of only the cobalt base solid solution. At higher chromium and tungsten contents various intermetallic phase would form in addition to the solid solution.

The carbon-tungsten-carbon system has been the subject of many investigations concerning cemented tungsten carbides (WC and  $\text{W}_2\text{C}$ ), dealing mainly with alloys containing less than 25% cobalt. However, Rautala and Norton<sup>13</sup> covered most of the alloy system and produced diagrams showing phase equilibria at  $1400^\circ\text{C}$ . These studies show that if the carbon content is maintained close to that required for stoichiometric formation of WC there will be a stable two-phase region of Co + WC below  $1400^\circ\text{C}$ . Carbon deficiencies lead to formation of  $\text{Co}_3\text{W}_3\text{C}$  while carbon excess leads to the formation of graphite. However, it has to be mentioned that up to  $\sim 7.5\%$  WC is soluble in cobalt.<sup>13</sup> Thus in alloys containing small quantities of carbon and tungsten, the formation of WC phase would not be expected.

### 3.06.1.5 Processing

There are numerous processing techniques depending on the application and the environment available to provide good wear and corrosion resistance parts from

cobalt base alloys. The effect of different processing techniques on the microstructure and the mechanical properties has been studied by different researchers and a short review is presented later in the chapter.

Wrought cobalt–tungsten base alloys were studied by Adkins *et al.*<sup>14</sup> In the binary alloys, the room temperature hardness increased with increasing tungsten content up to 15%. There was a slight drop in hardness for alloys containing over 15% tungsten. Solution-treated and quenched alloys showed a martensitic  $\text{Co}_3\text{W}$  phase.

Stellite alloys are often used as a coating for hard-facing applications or as castings. The casting and hard-facing of Stellite is, however, difficult and leads to an inhomogeneous coarse grain structure and also to excess dilution and improper adherence when there is overlaying.

Mohamed *et al.* studied the localized corrosion behavior of alloy Stellite 6 produced by hot isostatic pressing (HIP) and by wet powder pouring using electrochemical techniques.<sup>15</sup> In another work Wong-Kian *et al.* compared the erosion corrosion behavior of HIPed and welded Stellite coatings<sup>16</sup> and showed that HIPed alloys have lower mass loss due to finer microstructure. Malayoglu also confirmed the superior resistance of HIPed Stellite 6 and attributed this to the different microstructure with spherical carbides and the enriched Cr in solid solution in the matrix.<sup>3</sup> Figure 4 shows the HIPed microstructure of Stellite 6.

Frenk and Kurz<sup>17</sup> investigated the solidification conditions and microstructure of a cobalt base alloy.

They concluded that different processing conditions can be achieved using laser surface cladding. For example, a variation in the laser scanning rate over two orders of magnitude from  $1.67$  up to  $167 \text{ mm s}^{-1}$  led to a considerable refinement of the microstructure. Antony<sup>18</sup> compared the wear performance of various forms of Stellite alloy 6B. He showed that gas tungsten arc welded (GTAW) alloy had better cavitation resistance compared to investment cast, wrought and oxyacetylene Stellite 6B deposit. Berns and Wendl analyzed the microstructure of the alloy Stellite 6 in the cast, forged and powder metallurgy state and compared them to the mechanical and wear properties.<sup>19</sup>

Weld overlays are used for economic and technical reasons. From an economic standpoint, it is sensible to use relatively expensive wear and corrosion resistant alloys only where their properties are necessary. From a technical standpoint, many wear-resistant alloys are brittle by nature and thus unsuitable for use in bulk form. The largest problem associated with the use of weld overlay material is dilution that is, the intermixing which occurs with the substrate material, generally stainless steel. It has been reported that dilution of iron into the cobalt-base alloy is detrimental to the corrosion and cavitation resistance of cobalt-base alloys.<sup>20</sup>

Cobalt and cobalt–molybdenum binary alloys have been the subject of work by Bibring and coauthors.<sup>21</sup> In alloys containing 8% or 10% molybdenum, quenching results in a structure that consists primarily of the hcp low temperature phase, and a significant proportion of the fcc nonequilibrium high temperature phase. When aged at a temperature below the solubility limit, the supersaturated hcp phase increases rapidly in hardness, while the fcc phase remains unchanged. This selective hardening of the hcp phase is due to the appearance of a phase with a composition corresponding to  $\text{Co}_3\text{Mo}$ . Darby and Beck<sup>22</sup> investigated the cobalt–chromium–molybdenum alloys and they reported an existence of  $\text{Co}_{13}\text{Cr}_{17}$ , which had a beneficial effect on the mechanical properties of the alloy. Silverman *et al.*<sup>23</sup> increased the proportion of chromium and molybdenum in commercial alloy Stellite 21. They found that room temperature hardness increased with increasing proportion of chromium and molybdenum.

Precipitation of an intermetallic compound in cobalt–chromium–molybdenum alloys was found to increase the room-temperature hardness in alloys containing 20% chromium and up to 16% molybdenum. A study of precipitation hardening in alloys containing 12.0% to 17.5% chromium and from 15% to 20% molybdenum was made by Lux and

**Figure 4** Microstructure of HIPed Stellite 6 (e) Cr-rich carbides, (f) Co-rich matrix. Reproduced from Malayoglu, U. PhD Thesis, Heriot-Watt University, 2005.

Bollmann.<sup>24</sup> The alloys as-cast all contained a coarse precipitate of  $\text{Co}_7\text{Mo}_6$ . Some of the alloys in the cast condition showed Widmanstätten structure. It was suggested that this structure was associated with the formation of a  $\text{Co}_3\text{Mo}$  super lattice. Generally speaking, the precipitate observed in cast specimens that had been aged for 100 h at  $1000^\circ\text{C}$  gave an X-ray pattern that corresponded to  $\text{Co}_7\text{Mo}_6$ , but chemical analysis of precipitates indicated a partial replacement of the molybdenum by chromium. The amount of chromium in the precipitate increased with aging temperature. At room temperature, the data offered three possible relationships between the precipitate and the matrix: a  $\text{Co}_3\text{Mo}$  super lattice, a coherent  $\text{Co}_3\text{Mo}$  precipitate, or a coherent  $\text{Co}_7\text{Mo}_6$  precipitate.

### 3.06.1.6 Strengthening Mechanisms

Intermetallic compounds play an important role in the microstructure of Co-base alloys and the next few paragraphs discuss the nature of these and their role in affecting the properties of Co-base alloys.

Geometrically close-packed (GCP) phases are usually designated by the chemical formula  $\text{A}_3\text{B}$ , where A is the larger atom. For example, in nickel base superalloys a fine precipitate  $\text{Ni}_3(\text{Al},\text{Ti})$  contributes greatly to high temperature strength. Because of its strengthening characteristics and high solution temperature, this phase has improved tremendously the high temperature properties of nickel superalloys, and even surpassed the properties of the cobalt systems. The generation of GCP phases within cobalt alloys is substantially more difficult since the chemical and crystallographic stability is affected by a lattice mismatch that is rarely less than 1%. In contrast, topologically close-packed phases (TCP) are usually detrimental to high temperature mechanical properties of cobalt superalloys. These phases are made up of close-packed layers of atoms separated from one another by relatively large interatomic distances forming a characteristic topology. By contrast, GCP phases are characterized as close-packed in all directions. The most common TCP phases are  $\sigma$ ,  $\mu$ , and R which are electron compounds. The general formula for a TCP phase is:  $(\text{Co},\text{Ni})_x(\text{Cr},\text{Mo},\text{W})_y$ , where  $x$  and  $y = 1-7$ . The structure of the TCP-type phases ( $\sigma$ ,  $\mu$  and R) are as follows:

$\sigma$ = complex body centre tetragonal	30 atoms/unit cell
$\mu$ = rhombohedral	13 atoms/unit cell
R = rhombohedral	53 atoms/unit cell

Laves phases are the most common intermetallic compounds of the TCP type. The chemical formula for Laves phase is  $\text{A}_2\text{B}$ , where A and B are two different metallic elements and occur in high temperature superalloys when excessive amounts of refractory metals are added. These phases precipitate as both plate and block structures and are generally detrimental to mechanical properties.

The primary strengthening mechanism in cobalt base alloys is precipitation hardening; principally by the presence of carbides in the matrix and grain boundaries. The carbides, especially  $\text{M}_{23}\text{C}_6$ , precipitate at the grain boundaries, pin the grain boundaries preventing grain boundary sliding, or in the case of higher carbon content, the carbide network may support some of the load. The large carbide particles can act as dislocation generators under the influence of a stress and the subsequent dislocation interaction can give rise to an increase in the flow stress of the metal. Regarding carbides, another important mode of strengthening arises from precipitation of fine  $\text{M}_{23}\text{C}_6$  particles on stacking faults. This provides a rather uniform dispersion of interlocking structural effects caused by the hard carbide particles at stacking faults and stacking fault intersections.

Beside carbides, another form of second phase particles in cobalt-based alloys are intermetallic compounds as mentioned earlier. These phases have to be considered as they can cause a significant loss of both strength and ductility. Their deleterious effect is due primarily to the chemical partitioning effect caused by the mass presence of the phase itself, thus depleting the matrix of solute-strengthening atoms. As mentioned earlier, solid solution strengtheners include mainly the refractory elements such as chromium, molybdenum and tungsten. These atoms contribute to strengthening in a number of ways: they inhibit recovery by binding vacancies; and also they impede dislocation glide through the existence of interstitial complex around the refractory atoms. The fcc-hcp transformation in cobalt alloys has not been fully utilized in the development of desired mechanical properties. This is primarily due to the fact that the details of the allotropic transformation have not been well understood. The first detailed examination using transmission electron microscopy of the fcc-hcp transformation in the Co-Cr-Mo-C system was carried out by Vander Sande *et al.*<sup>25</sup> Their work was initiated by earlier findings of property modifications in response to heat treatment and processing variables and associated microstructural changes.

### 3.06.2 Corrosion

#### 3.06.2.1 Electrochemistry

Compared with iron, cobalt is significantly more noble and part of its domain of stability lies above the hydrogen stability line for water. Compared with nickel, it is slightly less noble; the main difference in chemistry being a considerably larger stability for the Co(III) oxidation state compared to the corresponding nickel species. Cobalt is passive in neutral to alkaline pH but dissolves in aerated and deaerated acids below pH 7. The Pourbaix diagram for cobalt is shown in Figure 5.

#### 3.06.2.2 Passive Films on Co-Base Alloys

It is generally acknowledged that the susceptibility of passive metals to localized corrosion (including pitting) and the rate at which this corrosion process occurs are closely related to the ability of the passive film to resist breakdown and to repassivate once corrosion has initiated.<sup>26</sup> The chemical composition of the passive film, its structure, physical properties, coherence and thickness are of paramount importance in the nucleation and propagation of localized corrosion.

Investigations into the composition and structure of passive oxide films on stainless steels and other related passive alloys, of which the Co-base superalloys are one class, are much more difficult than in

the case of analysis of oxide films on iron because the films are thinner, their chemical composition is complicated, and they cannot be reduced cathodically. A major part of the information available on composition and structure of passive films on stainless steels has been obtained with spectroscopic techniques, particularly X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES). Other methods such as ion scattering spectroscopy (ISS) and secondary ion mass spectrometry (SIMS) also provide valuable data.

The XPS method was used to study the composition and structure of oxide films on iron-chromium alloys. Li *et al.*<sup>27</sup> used this method to compare the film formed on Fe–30Cr and Fe–30Cr–2Mo alloys during passivation in 1 M KCl. They did not find any substantial differences in the film composition, which was primarily hydrated chromium oxyhydroxide. XPS and AES methods were also used by Olefjord and Elfstrom to study oxide films on austenitic stainless steels passivated in 0.1 M HCl + 0.4 M NaCl solution.<sup>28</sup> The passive film consisted primarily of chromium oxide. Iron was preferentially dissolved even during passivation. Mo enrichment was observed in high Mo alloyed (6%) steel. Ni was present only to a small extent in the film.

Compared to the extensive literature on Fe-based alloys (especially stainless steels) there is very little information available on other alloys which exhibit

**Figure 5** Pourbaix diagram for cobalt at a metal ion concentration of  $10^{-5}$  M.

passivity (e.g., Ni and Co-based alloys). Hocking *et al.*<sup>29</sup> studied the corrosion of Stellite 6 in lithiated high temperature water used in pressurized water reactors (PWR) coolant circuits. By using XPS, they determined the chemical composition at the outer surface of the corrosion layer and concluded that oxidation of Stellite 6 alloy is believed to occur by preferential dissolution of Co at the solution interface, leaving a Cr-rich oxide. An increase in oxygen activity leads to a change in the mechanism from diffusion controlled to solution transport, dissolution-precipitation process and the corrosion rate increases.

McIntyre *et al.* also studied on the formation of the corrosion film on Stellite 6 alloy<sup>30</sup> According to their work there are two major mechanisms controlling the corrosion behavior of the alloy during aqueous oxidation. One is migration via solid-state processes, while a second results from dissolution of the cation and its subsequent reprecipitation on the oxide surface. As a result of their work, they concluded that during aqueous exposure in either reducing or mildly oxidizing conditions, a depletion of the cobalt surface composition was observed. This implies that there is a preferential dissolution of cobalt, which had already migrated preferentially to the interface.

It is also known for passive alloys that there is generally an inverse relationship between the thickness of the film and its protective property. This was seen in work by Malayoglu *et al.*<sup>3</sup> where the breakdown potential in anodic polarization tests was shown to be reduced aligned with a thinning of the passive film detected by XPS on HIPed Stellite 6 in 3.5% NaCl.

For the as-polished sample of Stellite 6, the C 1s spectrum revealed the presence of an overlay of carbonaceous contamination, and the O 1s spectrum the presence of oxide/hydroxide species at the surface. The carbon contamination and oxygen-containing species are readily removed by argon etching. The C 1s spectrum also reveals the presence of metal carbide species below the contamination over layer. The Cr 2p spectrum comprises the presence of Cr metal, carbide and oxide/hydroxide species and the W 4f spectrum is consistent with the metal but not W oxides. The Co 2p spectrum is consistent with the presence of Co metal and oxide/hydroxide species. The XPS signals of the metal oxide/hydroxide species decrease with argon ion etching, hence the model for the as-polished surface is of a matrix of metal and metal carbide species with an over layer of Cr and Co oxide/hydroxide and carbonaceous contamination.

The analysis of the spectra after anodic polarization on HIPed Stellite 6 indicates a multilayer duplex structure, where the composition changes continually with depth. At the outer surface, the film contains no metallic Co, Cr or W and consists of  $\text{Cr}(\text{OH})_3/\text{Cr}_2\text{O}_3$  and  $\text{WO}_2$ . Immediately beneath this layer, depending on the test temperature, the film is composed of Cr  $(\text{OH})_3/\text{Cr}_2\text{O}_3$  and metallic Cr, from the bulk material can be observed. Similarly, W was detected in the form of  $\text{WO}_3$  and metallic W. A schematic representation of the key components of the air-formed film and corroded surface was presented as shown in Figure 6.

Maffiotte *et al.*<sup>31</sup> confirmed the qualitative similarity in oxide film composition on a 30%Cr, 4.5%W, 2.5% Ni alloy when exposed to different environments representative of operating conditions in PWR. The film in both solutions was Cr-enriched and Co-depleted but the depth profile of the oxide film composition was dependent on the solution composition. Longer exposure to the solution further enriched the oxide with Cr as shown in Figure 7.

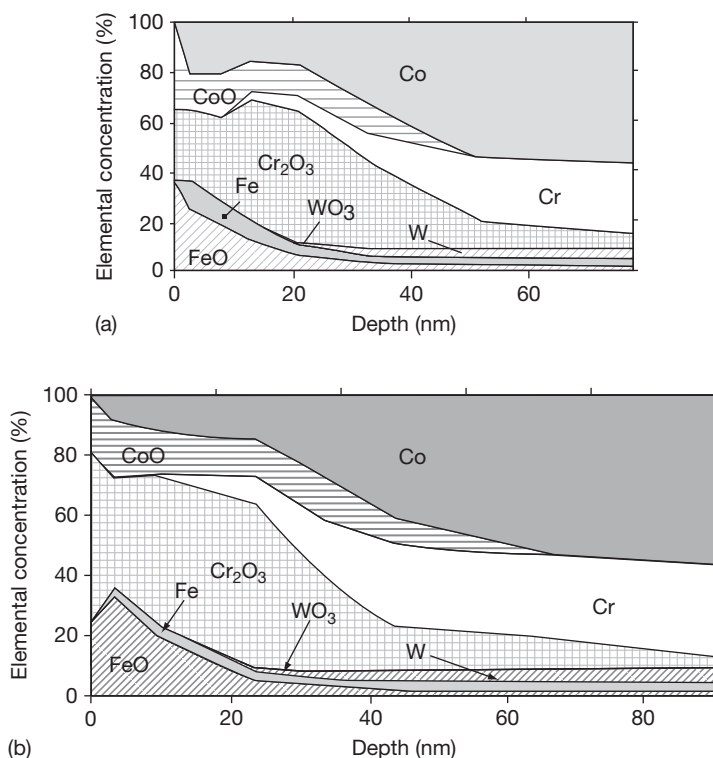

### 3.06.2.3 Corrosion of Cobalt-Based Alloys

Co-base alloys have seen extensive use in wear environments mainly due to their high strength, corrosion resistance and hardness. Application of cobalt-based superalloys was traditionally most prevalent in the nuclear industry in the 1960s and 1970s and, for this reason, much research into corrosion of Stellite was focused in conditions relevant to nuclear power applications such as simulated pressurized water reactor and primary heat transfer conditions, for example.<sup>32</sup>

Currently, use of Stellite alloys has extended into various industrial sectors (e.g., pulp and paper processing, oil and gas processing, pharmaceuticals, chemical processing) and the need for improved

**Figure 6** Key components of the air-formed passive film. Reproduced from Malayoglu, U. PhD Thesis, Heriot-Watt University, 2005.

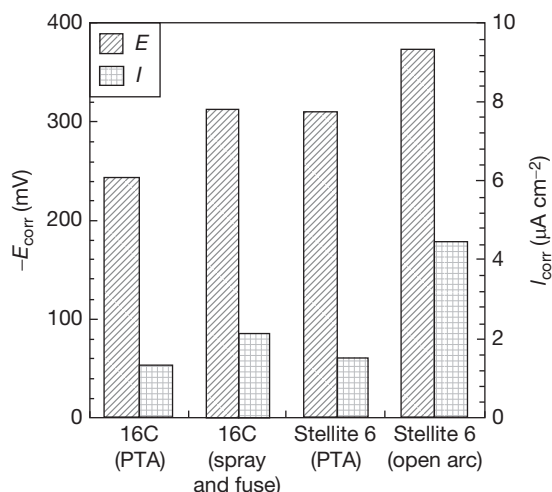

**Figure 7** XPS composition depth profiles from Stellite 6 immersed in 300 ppm  $\text{H}_2\text{BO}_3$ , 2.65 ppm  $\text{LiOH}$ , 2 ppm  $\text{H}_2$  for 250 h (a) and 2000 h (b). Reproduced from Maffiotte, C.; Navas, M.; Castaño, M. L.; Lancha, A. M. *Surf. Interface Anal.* **2000**, 30(1), 161–166.

information regarding corrosion (and often tribo-corrosion) of Stellite alloys has increased. It has been recognized that processing changes, which affect the microstructure of Stellite alloys, affect the corrosion behavior. Stellite alloys have been used as surface engineering systems as weld overlays, laser-clad overlays and HVOF coatings, and because of the very different microstructures as a result of the thermal cycling, the corrosion properties can vary. In a study by Kim and Kim<sup>33</sup> the corrosion resistance of Stellite 6 resulting from the plasma transferred arc (PTA) welded surfaces was compared to spray-fused and open arc-welded surfaces. Their corrosion results showed that the corrosion resistance of PTA weld surfaced Stellite 6 is better than that of the open arc weld surfaced Stellite 6 because dilution ( $\sim 15\%$ ) with the iron substrate for the open arc weld surfaced Stellite 6 is higher than that ( $\sim 5\%$ ) of the PTA weld surface Stellite 6. **Figure 8** shows the increase in corrosion current density ( $i_{\text{corr}}$ ) for the alloys experiencing higher dilution.

Mohamed *et al.*<sup>15</sup> studied the localized corrosion behavior of powder metallurgy processed cobalt-base

alloy Stellite 6 in a chloride environment. They showed that the Stellite 6 alloys produced by the HIP technique had the highest pitting and crevice corrosion resistance compared with identical alloys manufactured by the rolling or wet powder process. They discussed how the Oldfield–Sutton model of acidification was more appropriate for crevice corrosion in HIPed alloys than the models used to describe  $\text{Cl}^-$  accumulation. The finer microstructure for the HIPed alloy was thought to be the main reason for the improved resistance.

Human *et al.*<sup>34</sup> studied the electrochemical polarization and corrosion behavior of a cobalt–tungsten–carbon alloy in 0.5 M sulfuric acid. They showed that tungsten and carbon additions influence the corrosion behavior of the alloy. With increasing tungsten and carbon additions, the corrosion current density and the critical current density were reduced. The corrosion potential shifted to more positive values with increasing additions. As the corrosion studies have not necessarily been made with high purity elements, the effect of small amounts of impurity or alloying elements and the synergistic

**Figure 8** Comparisons of free corrosion potential and corrosion current density for surface engineered Stellite alloys in 3%NaCl. Reproduced from Kim, H. J.; Kim, Y. J. *Surf. Eng.* **1999**, 15, 495–501.

effects of them on the corrosion performance of the metals and alloys is difficult to determine and understand.

In this work empirical relationships were developed for the alloys of the form

$$E_{\text{corr}} = -372 + 70V_v^{\text{fcc}}(C, W)[\text{mV}]$$

where  $V_v^{\text{fcc}}$  is the volume fraction of fcc phase. In this nonpassivating system, the cracks and pores in the surface layer are clearly visible (**Figure 9**).

Malayoglu assessed the corrosion resistance of three Stellite alloys in the cast and HIPed form. The Stellite 12 has a similar composition to Stellite 6 but with a much higher content of W of 9%. In Stellite 706, the W in Stellite 6 is replaced with Mo. As shown in **Figures 10a and 10b** the resistance to passivity breakdown ( $E_b$ ) is affected by temperature and the alloys are affected to a different extent. At low temperature for the cast alloy Stellite 12 and Stellite 706 are comparable and more resistant than Stellite 6. Between 30 and 40 °C, there is a significant loss of resistance for Stellite 6. In potentiostatic tests on HIPed alloys, it was shown that the critical temperature was higher for Stellite 12 and Stellite 706. However, severe tunneling pitting was seen on Stellite 12 – not seen on Stellite 6.

#### 3.06.2.4 Oxidation

The effect of alloying elements on the high temperature corrosion performance of the metals and

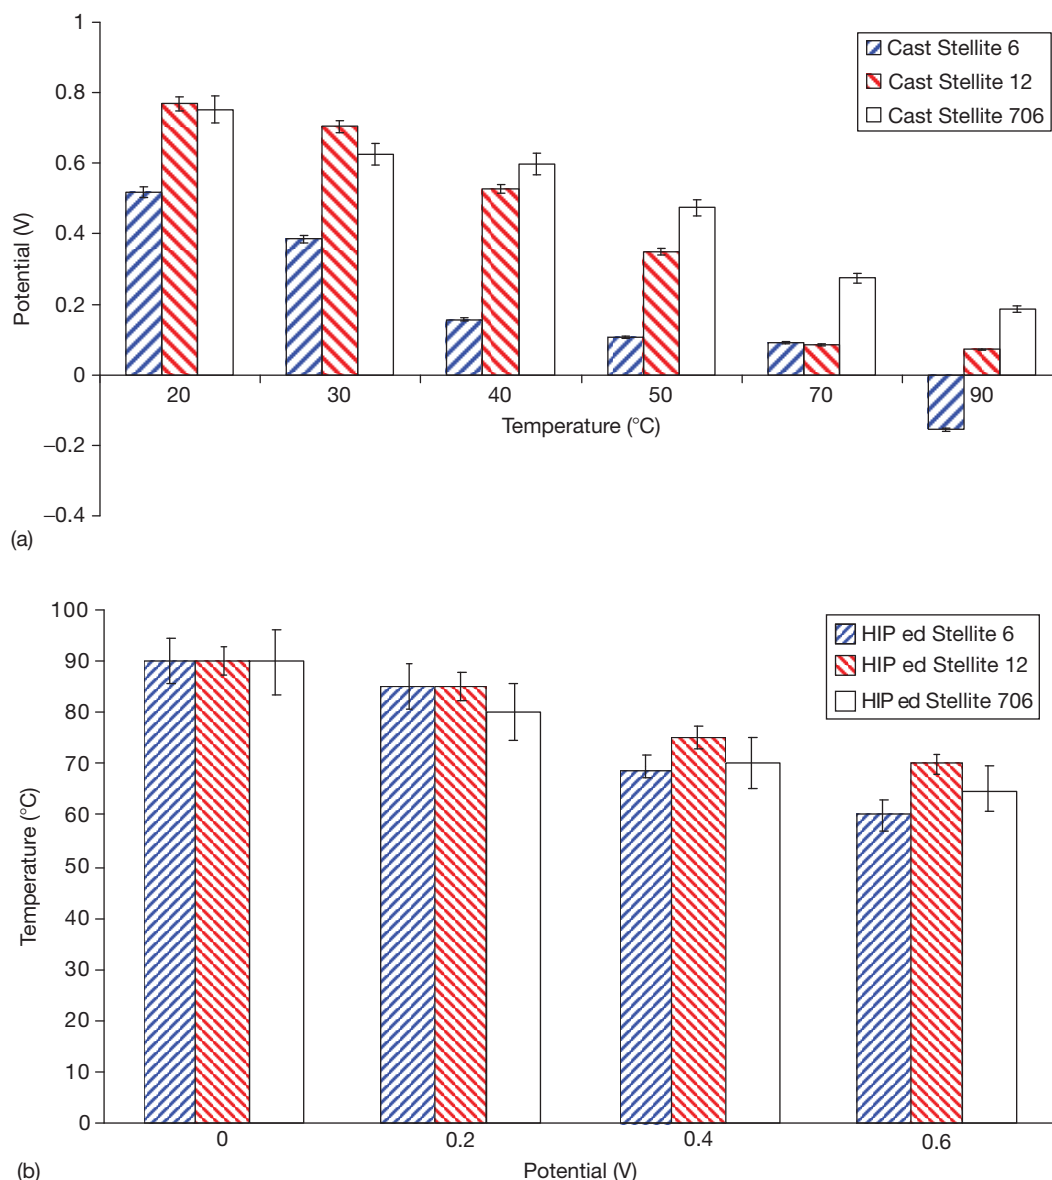

**Figure 9** Cracks and pores in the surface layer of Co—WC alloy in sulfuric acid. Reproduced from Human, A. M.; Roebuck, B.; Exner H. E. *Mater. Sci. Eng.* **1981**, A241, 202–210.

alloys, and the corrosion resistance of films and scales have been summarized by Frantsevich<sup>35</sup> who stated that;

- Small amounts of alloying elements will affect the parent metal oxide by changing its conductance. Factors influencing this will be the alloying element's valence, ion radius, and the heat of formation of the oxide.
- Large amounts of alloying elements will affect, more significantly, the properties, such as: electrical conductivity, mechanical and thermodynamic stability, and mutual solubility of the oxide phase. Changes in the dissolution pressure, concentration defects in the lattice, appearance of physical defects in the scale owing to stresses originating in the oxide film can be expected.

The effects of the alloying elements on improving the oxidation resistance of an alloy may be due to one or more of the following main factors:

- Reduction of the diffusion rate of reaction components in the oxide layer and metal through the decreased concentration of lattice defects and the formation of new phases of combined oxides.
- An increase of the ion mobility in the oxide may improve the mechanical properties of the scale phase and permit some plastic deformation.
- The decrease of the metal/oxide volume ratio, due to the change of parameters of the oxide and metal lattices, occurs when the cations are replaced with ions of smaller radii.

### 3.06.2.5 Corrosion in Biomedical Applications

#### 3.06.2.5.1 Joints

CoCrMo alloys have been widely and successfully used in hip joints due to their high corrosion resistance and good mechanical properties. Many authors have studied effects of the microstructure and elemental content on the joint-bearing performance. It has been shown that many factors influence their performance.<sup>36–39</sup> However, one major concern

about the use of CoCrMo alloys is the toxicity of the released Co and Cr ions. From clinical examinations, released metal ions lead to various phenomena: transportation, metabolism, accumulation in organs, allergic reactions, and carcinoma. If a large amount of metal ions are released, it is generally thought to be harmful to human health.<sup>40–42</sup> Some researchers have found Co, Cr, and Ni ions can be eliminated through urine.<sup>43</sup> Nevertheless, how they affect different organs, and the safe level of metal ions, are still

under investigation. Their effects are thought to be also dependent on the individual. Since the release of metal ions depends on the electrochemical reactions or on tribocorrosion processes, a full understanding of how corrosion and wear processes lead to the loss of ions from the surface is necessary.

Many authors have been studying metal on metal wear behavior *in vivo* and *in vitro*. A running-in (or bedding-in, wearing-in) stage is found for most cases, followed by a lower wear rate steady-state.<sup>44</sup> The length of running-in varies depending on the different simulators and geometry of contacts (pin-on-plate, ball-on-plate, etc.) from thousands of cycles to one million cycles.<sup>44–46</sup> Small wear debris particles are created in the running-in phase and cause abrasive wear. From clinical examinations, for the first few days after implantation of metal-on-metal joints, metal ions were found to increase dramatically. The metal ion level then stabilized,<sup>47–49</sup> which is possibly related to differences between the running-in and the steady-state phases phenomena and the saturation of metal ions in the body.

Corrosion has been considered as one of the major problems for metallic biomaterials. When devices are implanted into the human body, they are immediately surrounded by biological fluids. Even though corrosion can occur on plastics, ceramics, and glasses, the term is often associated with metals. In this section, corrosion of metallic bio-implant materials is the focus. From a corrosion engineering point of view, these liquids are not as aggressive as some industrial process fluids, but the body is still a harsh environment due to the oxygenated saline solution and the involvement of organic species. Ever since metallic biomaterials were adapted for surgical use, studies have been done to assess corrosion resistance of those materials. Three major metallic materials; stainless steel, cobalt chromium alloys, and titanium/titanium alloys are normally used and the understanding of their performance and improvement has been under investigation for several years.

Corrosion can severely limit the fatigue life and ultimate strength of materials, leading to the mechanical failure of implants. Corrosion has been implicated in causing local pain and swelling in the region of the implant and affect the performance of those implants resulting in failure and revision. The release of ions from implanted metallic biomaterials to the local host environment is also a great concern. Ions are released by chemical and electrochemical processes (corrosion).

One point which should not be ignored is the corrosion of wear debris. Even though nano-size

metal debris is very difficult to be collected and analyzed, it is still a potentially important source of the metal ion release which has not largely been studied until now.

The corrosion mechanisms of these metallic materials for surgical use have been extensively investigated, from both *in vitro* experiments and *in vivo* observations.

**Pitting corrosion:** Pitting corrosion is the most common type of localized corrosion. It was found on stainless steel implant materials resulting in extensive damage and causing release of significant amounts of metal ions.<sup>50</sup>

**Crevice corrosion:** Compared to the other types of metallic implant materials, Type 316L stainless steel is highly susceptible to this corrosion attack. In the area of contact between stainless steel screw heads and the bone plate, the occurrence of corrosion was found. It also induced crack propagation of bone plate.<sup>51</sup>

**Fretting corrosion:** Fretting corrosion phenomena are associated with micromotions between components.<sup>52</sup> When an oscillating rubbing action is continuously applied on two opposing surfaces such as bone plates and the screw heads of the prosthetic devices, fretting corrosion can occur.<sup>53</sup> It is the major factor to cause the initiation of cracks and fracture failures for surgical screws.

### 3.06.2.5.2 Galvanic corrosion

When metals of different types from different devices are in physical contact in body fluid, galvanic corrosion can occur. For example, a bone screw and a bone plate made of dissimilar metals and alloys can form a galvanic couple.

**Wear-corrosion:** When implant materials are under cyclic loading, wear-corrosion is always present.<sup>54</sup> Wear-corrosion resistance is an important factor of consideration for load-bearing surgical implants such as hip and knee replacement implants.

Metallic materials used for bearing surfaces in hip arthroplasties normally rely on a stable passive film, which forms spontaneously in air, for their biocompatibility. The passive film can form a barrier, which can efficiently separate the metal from the corrosive environment and protect it from further corrosion processes. The passive film inhibits corrosion and keeps current flow and the release of corrosion products at a very low level. Nonetheless, the release of metal into the body is a well-documented fact. Uniform passive dissolution resulting from the slow diffusion of metal ions through the passive film, trans-passive dissolution under high oxidizing conditions,

or the local breakdown of passivity as a consequence of localized forms of corrosion such as pitting or crevice corrosion, or as a consequence of mechanical events, such as fretting and wear corrosion, are all possible mechanisms.

XPS and other surface analysis techniques have been used to determine the nature of passive films on Co-base alloys. Primarily  $\text{Cr}_2\text{O}_3$ ,  $\text{CoO}$ , and  $\text{MoO}_3$  are found in the top layer (1.6 nm) of the spontaneously formed passive film in air for CoCrMo alloys. The inner layer of the passive film contains  $\text{Cr}_2\text{O}_3$  and Co and Mo metal species.<sup>55</sup> The total thickness of the passive film on CoCrMo alloys in the atmosphere is  $\sim 4\text{--}5$  nm.

Hanawa *et al.*<sup>56</sup> examined the surfaces of metallic stainless steel, CoCrMo alloys, and titanium. A preferential release of Co ion for CoCrMo alloys and Fe ion for stainless steel 316L were obtained. The release of Mo in CoCrMo was reported to be insignificant. A ratio of approximately 2.9:1 of Co/Cr for pin-on-disk tests on CoCrMo was reported.<sup>57</sup> However, the amount of Co released from cast CoCrMo alloys was found to be very small in the biological solution.<sup>58</sup> In addition it was found that the amount of Ni released from 316L gradually decreased with increasing pH; similarly, the amount of Cr and Mo ions released from CoCrMo decreased at pH 4 and higher. One thing which should be noticed is that, in the natural body serum condition, the pH is  $\sim 7.4$ . Calcium phosphate was found as precipitates on implant metals and alloys surfaces. They also suggested that the formation of oxide or hydroxides of metal ions was less toxic than the complex of protein-bond-metal.<sup>59</sup>

The CoCrMo alloys are highly corrosion resistant with only a minimal susceptibility whilst stainless steel quite readily suffers crevice and pitting corrosion. CoCrMo alloys are considered biocompatible. However, very high levels (20–30 times as reference normal serum cobalt value ( $0.15\text{ }\mu\text{g l}^{-1}$ ) and serum chromium value ( $0.26\text{ }\mu\text{g l}^{-1}$ )) of metal ions are reported cytotoxic with increasing concern over the biocompatibility of implant materials and especially in terms of the significance of corrosion, wear, hypersensitivity and carcinogenicity.<sup>60</sup> The quantity of organometallic production over longer periods after total joint replacement (TJR), correlation with patient health medication and activity levels remain the objective of many studies.<sup>61</sup> There can be no doubt, therefore, that patients with metal-on-metal (MoM) implants will be exposed to elevated levels of metal ions locally. The outstanding question is the clinical impact of these elevated ion levels. Brondner *et al.*<sup>62</sup> examined patients with CoCrMo MoM total hip

replacement (THR) and found that the Co and Cr concentration in blood serum and urine are high. They seem to fall after the initial one-year running-in phase. Average preparative blood serum cobalt levels of  $0.15\text{ }\mu\text{g l}^{-1}$  were cited as reference values for patients who had MoM hip implants from Muniz's studies on elements trace<sup>63</sup> and it is generally in line with the others. Black *et al.*<sup>64</sup> showed a disagreement concerning 'normal' levels for these elements in serum. Because it is still unclear what constitutes a normal level for an individual patient and what the consequences are of transient or chronic deviations from that level, a question mark still exists over MoM implantation.

Visuri and Koskenvuo<sup>65</sup> showed that there was no increase in the risk of cancer in patients with McKee-Farrar type CoCrMo MoM THR and Willert<sup>66</sup> found no proof that the release of metal is teratogenic but did show the possibility of hypersensitivity to metals. Koegel and Black<sup>67</sup> and others disagreed. An increased incidence in cardiomyopathy (a disease or disorder of the heart muscle) and tumors was found from animal tests. Because the number of patients with a MoM TJR for 10, 20, or more, years increases, it suggested that long-term studies are still required to fully address the issue of metal-ion associated diseases. Investigations to clarify the importance of toxicology are currently being undertaken by many researchers and clinicians.

Electrochemical methods have been employed to understand corrosion behavior for implant materials and then to assess their biocompatibility. Many authors have been trying to monitor the performance of TJR by measuring metal levels.<sup>68–69</sup>

At this stage, it is important that a more detailed understanding of the effects of implanted metals must be gained.<sup>69</sup> A wide variety of serum proteins exists *in vivo* and it is reasonable to assume that many of these become rapidly adsorbed onto the metal surfaces upon implantation. It is suggested that the adsorbed proteins influence the material corrosion rate.

### 3.06.2.6 Erosion-Corrosion

In certain environments, either where two moving surfaces come into contact or where there is impingement of a slurry onto a surface, wear is unavoidable. There is usually progressive deterioration of the surface resulting from the removal of material by at least one of the following mechanisms, abrasion, erosion, and erosion-corrosion. Additionally, forms of corrosion may occur locally to exacerbate the damage.

Neville *et al.*<sup>70</sup> discussed the effect of temperature on the erosion rate of Stellite X40 and BS 3468 cast

iron in the slurry erosion conditions. The focus of this work was to validate the use of Stellite X40 as an optimum material for subsea drill bit castings (Figure 11). Drill bits for subsea use have to be able to tolerate the impingement of the drilling fluid injected through the nozzle onto the faces of the bit which contain the diamond cutters. Material loss in this region is serious as the support for the cutters is lost, as seen in Figure 11(b). In their work, it was shown that the damage on the face is a complex mix of erosion and corrosion processes and that Stellite X40, is in fact the optimum material when compared with a variety of Fe and Ni base materials.

The synergistic effect between erosion and corrosion has received more and more attention in recent years because of the widespread occurrence of such problems in material processing industries. In such conditions, material selection can be a problem and, in many cases, is only carried out on the basis of empirical evidence. Erosion-corrosion can cause high material degradation rates because the action of the erodent particles can remove a stable passive film on the surface of the material. Hence, the wastage rates of the material can be significantly higher than the combined effects of erosion and corrosion acting separately.

The literature has not been consistent in the use and meaning of the synergistic effect in aqueous erosion-corrosion. Some authors describe it as the sum of the enhancement of erosion due to corrosion and vice versa ( $dE_C$  and  $dC_E$ ).<sup>71</sup> Some authors used the term

‘additive effect’ to refer to an enhancement, but there is a difference between these two terms. Often an ‘additive effect’<sup>72</sup> is when the sum of pure erosion in the absence of corrosion ( $E$ ), the pure corrosion in the absence of erosion ( $C$ ) and the change of corrosion rate due to erosion ( $dC_E$ ) is equal to the total weight loss (TWL). If this is not the case the ‘synergistic effect’ is observed. In other words, the term synergism is restricted to the erosion enhancement due to corrosion ( $S$  or  $dE_C$ ). The following equations [2] and [3] show the differences between the additive effect and the synergy ( $S$ ) effect from on which this work is based.

$$\text{TWL} = E + C + dC_E + dE_C \quad [2]$$

$$\text{TWL} = E + C + S \quad [3]$$

In order to define the synergistic effect, both erosion and corrosion must be studied independently of each other under controlled conditions. To obtain the corrosion rate, a potentiostat or galvanostat is used to control the electrical potential or current of the erosion sample.

Neville *et al.*<sup>70,73,74</sup> used a range of engineering alloys ranging from low grade C-Mn steel to super alloys, Stellite X40, to calculate the percentage damage caused by synergy.

They measured the TWL at the free corrosion potential; anodic polarization with presence of liquid–solid impingement and by using Tafel extrapolation *in situ* pure corrosion component of TWL ( $C$ )

(a)

(b)

**Figure 11** New subsea drill bit (a) and erosion-corrosion of the Stellite X40 around the polycrystalline diamond cutters (b).

is calculated. By applying a cathodic potential to the sample the pure erosion component ( $E$ ) of the TWL was obtained.

The TWL of the material was identified as pure erosion, corrosion and synergistic effects. In the literature, the effect of temperature, salinity, and solid particles content in the impingement jet was analyzed and their effect on the different mechanisms were quantified. Das *et al.*<sup>75</sup> showed that the corrosive wear rate increases with increasing angle of inclination and a higher wear rate was obtained for the impingement angle  $90^\circ$  and, the lowest weight loss was obtained at  $30^\circ$ . Similar findings were reported by Fan *et al.*<sup>76,77</sup> where they related these findings to the properties of the passive film. They showed that in the areas where the tangential component of impact velocity is large, the main mechanism is a cutting mode. On the contrary, in the areas where the normal component of impact velocity is larger, the failure mode consists of the formation of micro-cracks and the removal of second phases.

The performance of the different alloys under erosion-corrosion conditions has been studied with various techniques. Important variables relating to erosion such as load, fluid velocity, impact angle and solid loading have been studied to determine the erosion-corrosion behavior of materials. However, there is virtually no information available on cobalt-based superalloys under erosion-corrosion conditions and in particular, the effect of alloying elements on the mechanical and electrochemical damage, which is one of the main objectives of the current project.

### 3.06.2.7 Wear and Wear-Corrosion of Cobalt-Base Alloys

Cobalt-base alloys have enjoyed extensive use in wear-related engineering applications for well over 50 years because of their inherent high-strength corrosion resistance and ability to retain hardness at elevated temperatures. In recent years, a concentrated effort has been made to understand the deformation characteristics of cobalt-base alloys exposed to erosive environments in order to optimize those factors contributing to their erosion resistance.

In Stellite alloys the cobalt-rich solid solution incorporating elements such as chromium, tungsten and molybdenum, is highly resistant to erosion. This is due to rapid increase in the work hardening rate and the strain to fracture, which are caused by deformation

twinning and presence of a small amount of strain-induced  $\epsilon$  phase.

The wear properties of the cobalt-based alloys are believed to be influenced by:

- the limited mobility of the stacking faults generated by mechanical stress, which limits plastic deformation;
- interaction between stacking faults (this results rapid hardening);
- mechanical twinning which occurs extensively in certain alloys and absorbs energy;
- the formation of hcp platelets, which are believed to absorb energy; and
- the characteristics of this hcp phase once formed.

Most cobalt-based alloys possess good cavitation resistance and moderate abrasion and slurry erosion resistance. The last two features are independent of the carbon content, and have been attributed by Crook<sup>78</sup> to crystallographic transformation, under stress, from the fcc to hcp structure by twinning. During deformation, energy is absorbed and the effect of the stress is decreased.

Cobalt-based superalloys have been recognized as an alloy type one of the most resistant to both cavitation and liquid impact erosion.<sup>79</sup> The underlying reason for their superior erosion resistance behavior however, is not yet clear. Investigations have attempted to obtain universal correlation between the erosion resistance of the materials and the mechanical properties such as hardness and strain energy to fracture but all such attempts have been unfortunately unsuccessful. For example, austenitic stainless steel had higher erosion resistance than martensitic stainless steel of the same hardness and cobalt-base alloys had much higher resistance in relation to hardness.<sup>80</sup>

Lee *et al.*<sup>80</sup> compared the liquid impact erosion resistance of 12 Cr steel with a Vickers hardness of  $380 \text{ kg mm}^{-2}$  and Stellite 6B with a hardness value of  $420 \text{ kg mm}^{-2}$ . The liquid impact erosion resistance of Stellite 6B was at least six times greater than that of 12 Cr steel, implying that hardness is not the governing factor for liquid erosion. Stellite 6B also showed very different behavior in liquid impact erosion in comparison with 12 Cr steel (Figure 12). They concluded that the superior erosion resistance of Stellite 6B results from the cobalt matrix whose deformation appeared as mechanical twins. Other studies showed a trend of increasing erosion resistance with decreasing grain size. The twins are produced by the passage of partial dislocations, which had a Burgers vector equal to a fraction of the lattice vector, giving twinned

**Figure 12** Liquid impact erosion mechanisms of Stellite No. 6B.

regions and untwinned regions of different orientations. Therefore, the increase in density of twins with a number of impacts would play the role of fragmentation of the grains in the cobalt matrix into a submicrometer level. This would decrease the mean free path of dislocations to a limit surface distortion severely and given a much higher erosion resistance.

In the case of cavitation erosion, it is observed that the dynamic and localized nature of the stresses generated by the imploding cavities produce a material response which is quite different from that obtained under bulk quasi-static loading. A striking example of this is that cobalt and its alloys exhibit far greater erosion resistance than other metals and alloys comparable strength.<sup>81</sup> In fact pure cobalt is the most erosion resistant of comparable pure metals known.

Wong-Kian *et al.*<sup>16</sup> showed that under erosion-corrosion conditions HIPed Stellite alloys 1, 6, and 21 had lower mass loss than the welded specimens of the same Stellites. They related their finding to the finer and homogeneous microstructure, which was obtained after HIPing. They also showed that wear resistance of the cobalt-based alloys is promoted by the harder complex carbides of chromium and tungsten, while corrosion resistance is enhanced by the presence of cobalt in the matrix.

From almost all of the work done on the wear properties of Stellite alloys it has been concluded that the exceptional erosion resistance of the Stellite alloys can be ascribed to the drastic change in mechanical properties brought about by the formation of mechanical twins and by the presence of platelets of

the  $\epsilon$  hcp phase. It has been shown that the formation of twins and  $\epsilon$  phase is controlled by the SFE.

Strain hardening occurs as a result of interactions of dislocations with each other, and with barriers, which impede dislocation motion. One of the earliest explanations for strain hardening is that dislocations pile up on slip planes at barriers in the crystal, and produce a back stress, which opposes the applied stress on the slip plane.<sup>82</sup> Possible dislocation interactions and intersection of the active slip planes were suggested as another dominating mechanism for strain hardening. Mechanical twinning, and the presence of hcp platelets may also contribute to the work-hardening in cobalt base alloys. The effectiveness of each mechanism in terms of work-hardening depends upon the strain increment characteristics of each process. This concept was studied by Roebuck *et al.*,<sup>83</sup> who found the best strengths and ductilities in extruded Co-C-W alloys correspond with the highest fcc content. They suggested that when the fcc phase is stabilized deformation occurs by twinning or slip rather than by fcc-hcp martensitic transformation.

The strength of the matrix is considered in detail here. Kosel *et al.*<sup>84</sup> showed the effect of the matrix strength can affect the wear rate. They used the normalized alloy content (NAC) as a measure of the matrix strength. They defined the NAC as the sum of the weight percentages of Ni, V, W, Mo and in Table 2 they are normalized with respect to Stellite 6 alloy. The alloys that are used as solid-solution strengtheners give an approximate measure of the degree of solid-solution strengthening.

By using the same approach the NAC of the alloys Stellite 6, Stellite 12, and Stellite 706 were calculated and normalized against cast Stellite 6 as shown in Table 2.

Figures 13 and 14 show the change in the weight loss as a function of NAC. In Figure 12, only Stellite 6 and Stellite 12 are compared to assess the effect of increased tungsten on the NAC and the resistance to wear. Figure 13 is a comparison of Stellite 6 and Stellite 706 and the factor being considered here is replacing tungsten and molybdenum. From Figure 12 it can be clearly seen that an increase in the tungsten amount increases the NAC and the weight loss at both test temperatures and both solid loadings is not affected by the increase in NAC. However, as shown in Figure 13, there is a linear relationship between the NAC and the erosion-corrosion resistance of the alloys. The alloys with high NAC gave a lower weight loss in all test conditions. These two results show that molybdenum as a solid-solution strengthener is much more

effective in providing erosion-corrosion resistance than tungsten.

It is apparent that SFE has a significant influence in changing the deformation mode. The excellent erosion resistance of cobalt-based Stellite alloys is generally attributed to the low SFE,<sup>85</sup> which, in turn, means higher stacking fault probability and a greater chance for the formation of  $\varepsilon$  hcp platelets. The lower the SFE (the greater the width of the stacking fault) the more difficult is cross-slip, and the higher is the rate of work-hardening and the strain to fracture. Bhansali and Miller<sup>86</sup> examined the role of SFE on the galling and wear behavior of Stellite 6 modified by the addition of Ni, which in turn increases SFE and stabilizes the fcc matrix. Their results showed that materials with low SFE tend to strain harden rapidly, and to show the highest galling resistance.

Remy and Pineau<sup>87</sup> found that in Co–Cr–Ni–Mo alloys an SFE of  $\sim 20 \text{ mJ m}^{-2}$  resulted in an Md temperature (i.e., the maximum temperature at which the

fcc–hcp reaction can be stress induced of  $\sim 25^\circ \text{C}$ ). This low value of the SFE also gives rise to the optimum mechanical properties, that is, the highest work-hardening rate and the maximum strain to fracture.

Heathcock and Ball,<sup>79</sup> compared the cavitation erosion resistance of a number of Stellite alloys, (3, 4, 6, 8, 20, and 2006), cemented carbides and surface-treated alloy steels. They showed that among the Stellite alloys, Stellite 3 has the highest resistance to cavitation erosion. Stellite 4, 6, 8, and 20 have similar resistance and Stellite 2006 is a little less resistant than all the Stellite alloys. They considered this difference to be a consequence of the microstructure. Stellite 3 has carbides  $\text{Cr}_7\text{C}_3$  and  $\text{W}_6\text{C}$  which form a fine interdendritic network in a cobalt-rich matrix whereas in Stellite 20 acicular  $\text{Cr}_7\text{C}_3$  carbide formation and islands of cobalt-rich solid solution were observed. They also showed that acicular carbides in Stellite 20 are much harder than those in Stellite 3 (1860 HDP compared with 1100 HDP), which also showed the inverse relation between the hardness and the cavitation erosion resistance of the alloys. They concluded that in Stellite alloys the cobalt-rich solid solution, incorporating elements such as chromium, tungsten, and molybdenum is highly resistant to erosion, due to a rapid increase in the work-hardening rate and the strain to fracture which is caused by deformation twinning and the presence of a small amount of strain-induced  $\varepsilon$  phase.

Although some attempts have been made to correlate hardness with erosion resistance, a good

**Table 2** Normalized alloy content of Stellite 6, Stellite 12, and Stellite 706 (both cast and HIPed)

Alloy	Normalized alloy content (NAC)
Stellite 6 Cast	1
Stellite 6 HIPed	1.2
Stellite 12 Cast	2.5
Stellite 12 HIPed	2.4
Stellite 706 Cast	1.36
Stellite 706 HIPed	1.39

**Figure 13** Total Weight Loss (TWL) test results plotted versus normalized alloy content for Stellite 6 and Stellite 12. Reproduced from Malayoglu, U. PhD Thesis, Heriot-Watt University, 2005.

**Figure 14** Total Weight Loss (TWL) test results plotted versus normalized alloy content for Stellite 6 and Stellite 706. Reproduced from Malayoglu, U. PhD Thesis, Heriot-Watt University, 2005.

correlation generally has been recognized only for pure metals or alloys with the same compositional system. For example, Finnie *et al.*<sup>88</sup> showed that a good relationship between material hardness and erosion resistance existed for pure metals but not for heat-treated carbon steel (the erosion resistance was nearly constant, independent of the heat treatment). In another study, the cobalt alloy Stellite 6 B was shown to have a steady-state rate of volume loss, an order of magnitude less than many titanium- and iron-base alloys of comparable hardness.<sup>89</sup> These results may suggest that it is not possible to use material hardness as the sole parameter in evaluation of erosion resistance for all materials.

Frenk and Kurz<sup>81</sup> investigated the influence of the microstructure on the dry sliding wear resistance of a hypoeutectic Stellite 6 alloys. They showed that the hardness is dependent on the microstructure and in particular, on the size of the dendrites and the chemical composition of the matrix, in particular elements modifying the SFE. They reported a severe delamination wear of the Stellite under the sliding conditions investigated. During the stationary wear regime, no dependence of the wear rate on the as-solidified microstructure was determined. They suggested addition of alloying elements which decreases the SFE, which could improve the dry sliding wear resistance.

Desai *et al.*<sup>90</sup> studied the effect of carbide size on the abrasion resistance of two cobalt-based powder metallurgy alloys 6 and 19. As a result of their SEM investigation they divided the wear scar into three

parts, entrance, central, and exit regions. In the entrance region, many of the abrasive particles move at angles to the length of the wear scar, while in the central and exit regions the particles create long straight grooves. Stellite 6 gave a greater mass loss than alloy 19 at any given carbide size. They attributed this to the combined effect of the higher matrix microhardness of alloy 19. They also concluded that the wear rate decreased monotonically with increasing carbide size. The effect of carbide size is attributed primarily to the fact that the smaller carbides are often found to be contained wholly within micromachining chips, indicating that these carbides contribute little to wear resistance.

## Glossary

**Antimicrobial** Capable of destroying or inhibiting the growth of microorganisms.

**Dealloying** A corrosion process whereby one constituent of a metal alloy is preferentially removed from the alloy, leaving an altered residual microstructure.

**Dezincification** A corrosion process specific to brasses (copper–zinc alloys) whereby zinc is preferentially removed from the alloy, resulting in a porous residual microstructure.

**Shape memory alloy** An alloy which, after it is deformed, will automatically regain its original geometry when it is heated.

## Abbreviations

**BTAH** Benzotriazole

**FPSO** Floating production, storage and offloading vessel

**MIC** Microbiologically influenced corrosion

**MRSA** Meticillin-resistant *Staphylococcus aureus*

**SCC** Stress corrosion cracking

**SEM** Scanning electron microscopy

**STEM** Scanning transmission electron microscopy

**WHO** World Health Organization

## Symbols

**$A_i$**  Activity of species *i*

**$K$**  Equilibrium constant and rate constant

**$Q$**  Activation energy

**$R$**  Copper run-off rate

**$R$**  Gas constant

**$T$**  Temperature (K)

## 3.07.1 Introduction

Copper and copper alloys are among the earliest metals known to man, as they have been used from

prehistoric times, and their present-day importance is greater than ever before. Their widespread use depends on a combination of good corrosion resistance in a variety of environments, excellent workability, high thermal and electrical conductivity, and attractive mechanical properties at low, normal, and moderately elevated temperatures.

A wide range of cast and wrought alloys is available. For detailed expositions of properties and uses, the reader is referred to publications of many specialized aspects obtainable from the Copper Development Association offices in various countries. Relevant publications of the British Standards Institution include BSEN1982, *Copper Alloy Ingots and Castings*,<sup>1</sup> and those covering wrought products.<sup>2,3</sup> All ASTM standards relating to copper and copper alloys are included in a volume published annually.<sup>4</sup>

### 3.07.1.1 Alloy Compositions and Properties

The mechanical properties of wrought alloys<sup>5,6</sup> depend on composition and metallurgical condition. At the extremes, annealed pure copper has a tensile strength of  $220 \text{ MN m}^{-2}$  and a hardness of 40 HV, and heat-treated beryllium copper can have a tensile strength of  $1450 \text{ MN m}^{-2}$  and a hardness of 400 HV. Summaries of typical properties of some of the more important wrought and cast copper alloys are given in [Tables 1–4](#).

#### 3.07.1.1.1 Coppers

The purest grade of copper commercially available, and that with the highest electrical conductivity, is oxygen-free high-conductivity copper. The minimum copper content required by some specifications is 99.99% and the method of manufacture is such that no residual deoxidant is present. Oxygen itself has very little effect on conductivity, and the ‘tough pitch’ coppers (either electrolytic or fire-refined), containing ~0.04% oxygen are high-conductivity materials.

One disadvantage of tough pitch coppers is embrittlement, which is liable to occur when they are heated in atmospheres containing hydrogen. Therefore, for many purposes (and particularly where fabrication is involved) deoxidized coppers are preferred. The usual

deoxidizing agent is phosphorus, and specifications require residual phosphorus contents of between 0.004% and 0.06%. Phosphorus-deoxidized coppers with lower phosphorus content have electrical conductivities  $\sim 98\%$  of that of pure copper.

### 3.07.1.1.2 High conductivity coppers

Pure copper has the highest electrical conductivity of any metal apart from silver. However, it has poor strength and suffers from creep at temperatures above  $\sim 150^\circ\text{C}$ . A small addition of silver (0.03–0.12%) gives an increase in creep strength and resistance to softening up to  $250^\circ\text{C}$  (up to  $350^\circ\text{C}$  for short times). Copper–silver alloys are widely used in electrical motors and for contact and catenary wires for electric railways and tramways. They have a nominal conductivity of 100% IACS. In the past, copper–cadmium alloys (0.5–1.2% Cd), which have an excellent combination of strength and electrical conductivity, were widely used for such applications. However, due to health concerns regarding cadmium when the alloy is molten, the use of copper–cadmium alloys is declining. Other high conductivity alloys such as copper–magnesium and copper–tin (0.1–0.5%) have been developed. For all of these high conductivity alloys, a compromise has to be made between high strength and electrical conductivity.

### 3.07.1.1.3 Heat treatable copper alloys

Copper alloyed with 0.5–1.2% chromium with or without 0.03–0.3% zirconium gives precipitation hardening alloys with strengths up to  $450\text{ MN m}^{-2}$ . Such alloys have electrical conductivities of 80% IACS together with good thermal conductivity properties.

Precipitation hardening Cu–Ni–Si alloys are also available. One type is based on copper, nickel, and silicon (described as ‘High strength bronze’ in [Table 3](#)), which, with further alloy additions, can

reach tensile strengths of around  $800\text{ MN m}^{-2}$  while retaining its high conductivity. For this material, which is widely used for plastic moulding equipment, the main precipitating phase is  $\text{Ni}_2\text{Si}$ . Stress relaxation and the ability to withstand high temperatures under stress without losing spring properties or ease of bending are importance for this material.

The highest strength of any copper alloy (up to  $1450\text{ MN m}^{-2}$ ) is obtained by precipitation hardening and cold working copper–beryllium (1.8–2.0% Be). However, due to the toxic nature of beryllium, care must be exercised in melting and machining this alloy.

### 3.07.1.1.4 Brasses

Brasses are basically alloys of copper and zinc, containing between  $\sim 10\%$  and 45% Zn, but many other additions can be made.<sup>7</sup> The single-phase ( $\alpha$ ) brasses, containing up to  $\sim 37\%$  Zn in the binary alloys, may have additions of 1% Sn (Admiralty brass), 2% Al (aluminum brass), or 1–3.5% Pb for ease of machining. Duplex ( $\alpha$ – $\beta$ ) brasses containing more than 37% Zn, may have additions of 1% Sn (Naval brass), or 1–3% Pb to assist machining. Both  $\alpha$  and  $\alpha$ – $\beta$  brasses, with and without lead, are used in the cast as well as the wrought form. High-tensile brasses are  $\alpha$ – $\beta$  alloys containing up to 5% Al and 1–2% of one or more of the following: Sn, Pb, Fe, or Mn. These alloys also are used in both wrought and cast form.

### 3.07.1.1.5 Cupronickel alloys

Cupronickel alloys contain between 5% and 30% Ni and are mainly used in the wrought condition.<sup>8</sup> The more popular grades have 10% and 30% Ni and are recognized for their very good corrosion and biofouling resistance in marine applications.<sup>9,10</sup> Small controlled alloying additions of iron and manganese are essential to optimize their resistance to localized corrosion and seawater flow. The addition of chromium has also been shown to improve resistance to flow

velocity and a cast (30Ni–1.6Cr)<sup>11</sup> as well as a wrought version (16Ni–0.5Cr)<sup>12</sup> have been developed. The cast version has been predominantly used by the British Navy and is covered by DEF STAN 02-824.<sup>11</sup>

Other higher strength cupronickels have additions of aluminum or tin, producing two ranges of products. The Cu–Ni–Al alloys<sup>13</sup> are thermally age-hardened to form Ni<sub>3</sub>Al precipitates in the matrix whereas Cu–Ni–Sn alloys display spinodal strengthening through the development of submicroscopic chemical composition fluctuations.<sup>14</sup>

#### 3.07.1.1.6 Tin bronze

Copper alloys with 1.5–9% Sn and 0.01–0.4% P are wrought alloys known as phosphor bronzes. They have good elastic properties combined with good resistance to corrosion and corrosion fatigue.

Cast copper alloys with between 2% and 11% Sn and 1–10% Zn are termed gunmetals. Modified forms may contain lead (up to 7%) giving leaded gunmetal or nickel (up to 6%) giving a nickel gunmetal. Gunmetals are the most widely used copper casting alloys combining good corrosion resistance with modest strength and good castability.

#### 3.07.1.1.7 Aluminum-bronzes

Wrought aluminum bronzes contain between 4% and 12.5% Al. If less than 8% Al is present, the alloys are  $\alpha$ -phase and may be cold worked. The two phase ( $\alpha$ – $\beta$ ) alloys, which may be wrought or cast, contain 8–12.5% Al with possible additions of iron (0.5–7%), manganese (1.5–3.5%), nickel (2–7%), and silicon (2%). In terms of its influence on corrosion resistance, the addition of nickel is the most important, as it acts to reduce dealuminification (see [Section 3.07.3.3.3](#)).

Aluminum bronzes can be hardened by heat treatment and have an enhanced corrosion resistance due to the existence of a complex naturally-formed protective film which includes both aluminum oxide<sup>15</sup> and copper oxide. If damaged, the film is self healing and this gives aluminum bronzes good wear, cavitation, and antigalling characteristics.

#### 3.07.1.1.8 Silicon-bronzes

Silicon-bronzes usually contain 2.8–4.5% Si and 0.8–1.5% Mn. The wrought alloys combine high tensile strength (see [Table 2](#)) with good corrosion resistance and an attractive color. They are used in chemical equipment and marine hardware. The cast alloy has found application in statuary, art castings, and plaques.

#### 3.07.1.1.9 Nickel silvers

Nickel silvers do not contain silver but are essentially copper–zinc brasses with nickel in the range of 9–18%. The 18% nickel alloy polishes to a white color (like silver) and has good corrosion resistance. All have excellent ductility and are available as tube, wire, plate, sheet, and strip.

#### 3.07.1.1.10 Copper–nickel–chromium

Copper–nickel–chromium alloys have been developed chiefly as cast alloys, the most prominent of which is CC382H. A version of this is DEF STAN 02-824, which is commonly used by the British Navy.

### 3.07.2 Theoretical Aspects of Copper Corrosion

Copper is the first member of Group IB of the periodic table, having atomic number 29 and electronic configuration [Ar]3d<sup>10</sup>4s<sup>1</sup>. Loss of the outermost s electron gives the cuprous ion Cu<sup>+</sup> and a second electron may be lost from the filled d shell to form the cupric ion Cu<sup>2+</sup>. The availability of the d electrons for coordination allows copper to readily form complexes with such species as NH<sub>3</sub> and CN.

Copper occurs in the uncombined state in nature and is relatively easily obtained by the reduction of its compounds. It is not very active chemically and oxidizes very slowly in air at ordinary temperatures. In the electrochemical series of elements, copper is near the noble end and will not normally displace hydrogen, even from acid solutions. Indeed, if hydrogen is bubbled through a solution of copper salts, copper is slowly deposited, a process which occurs more rapidly if it is carried out under pressure.

As copper is not an inherently reactive element, it is not surprising that the rate of corrosion, even if unhindered by films of insoluble corrosion products, is usually low. Nevertheless, although the breakdown of a protective oxide film on copper is not likely to lead to such rapid attack as with a more reactive metal (e.g., aluminum), in practice the good behavior of copper, and, more particularly, of some of its alloys often depends to a considerable extent upon the maintenance of a protective film of oxide or other insoluble corrosion product.

In many environments, alloys of copper can be more resistant to corrosion than is copper itself, owing to the incorporation either of relatively corrosion-resistant metals, such as nickel or tin, or of metals such as aluminum or beryllium which would

be expected to assist in the formation of protective oxide films. Several types of copper alloys are liable to undergo a selective type of corrosion in certain circumstances, the most notable example being the dezincification of brasses (see [Section 3.07.3.3.2](#)). Some alloys are liable to suffer stress corrosion by the combined effects of internal or applied stresses and the corrosive effects of certain specific environments. The most widely known example of this is the season cracking of brasses (see [Section 3.07.3.6](#)). In general, brasses are the least corrosion-resistant of the commonly used copper-based alloys.

The various grades of commercial copper available do not differ to any marked extent in their corrosion resistance, and a choice between them is usually based on other grounds. Subsequent references to the corrosion behavior of copper may therefore be taken to apply broadly to all types of copper. The choice of alloy for any particular application is determined by the desired physical, mechanical, and metallurgical properties. Within these limits, however, a range of materials is usually available. It is essential that, at the very earliest stage, the choice of materials and the detail of design of the installation should be considered from the point of view of corrosion if the best performance is to be obtained in service. This is particularly true for copper alloys, where protective measures are not normally applied.

### 3.07.2.1 Electrode Potential Relationships

The electrode potentials for the equilibria:

are +0.34, +0.52, and + 0.17 V respectively, as measured against a standard hydrogen electrode. For the equilibrium

$K_c$  has the value of  $\sim 1 \times 10^6$  at 298 K, and in solutions of copper ions in equilibrium with metallic copper, cupric ions therefore greatly predominate over cuprous ions, except in very dilute solutions. Cupric ions are therefore normally stable and become unstable only when the cuprous ion concentration is very low. A very low concentration of cuprous ions may be produced in the presence of a suitable anion, by the formation of either an insoluble cuprous salt or a very

stable complex cuprous ion. Cuprous salts can therefore exist in contact with water only if they are very sparingly soluble (e.g., cuprous chloride) or are combined in a complex, for example,  $[\text{Cu}(\text{CN})_2]^{-}$  and  $[\text{Cu}(\text{NH}_3)_2]^{+}$ . Cuprous sulfate can be prepared in nonaqueous conditions, but because it is not sparingly soluble in water, it is immediately decomposed by water to copper and cupric sulfate. The equilibrium between copper and cuprous and cupric ion is disturbed by the presence of oxygen in solution, since the reaction shown in [eqn \[3\]](#) is facilitated, the oxygen acting as an electron acceptor.

### 3.07.2.2 Behavior of Copper Electrodes

The electrode potential behavior of copper in various solutions has been investigated in detail by Gatty and Spooner.<sup>16</sup> According to these workers a large part of the surface of copper electrodes in aerated aqueous solutions is normally covered with a film of cuprous oxide and the electrode potential is usually close to the potential of these film-covered areas. The filmed metal simulates a reversible oxygen electrode at the oxygen concentration and pH, less an overvoltage determined by the existing current density. The principal factors which affect the electrode potential are thus the nature of the solution, the way in which this influences the area of oxide film, and the supply of oxygen to the metal surface. In solutions containing chloride, there is a tendency for the establishment of the  $\text{Cu}/\text{CuCl}/\text{Cl}^{-}$  electrode potential, so that the activity of chloride ions is an important factor in determining the electrode behavior. From a knowledge of the solubility products of cuprous chloride and cuprous oxide, it is possible to predict under what conditions chloride or hydroxyl ions are the potential-determining ions. According to Gatty and Spooner, chloride determines the potential if  $a_{\text{OH}^{-}} < 10^{-8.1} \times a_{\text{Cl}^{-}}$  and hydroxyl determines the potential if  $a_{\text{OH}^{-}} > 10^{-8.1} \times a_{\text{Cl}^{-}}$ . However, this will not hold in concentrated solutions as complex  $[\text{CuCl}_2]^{-}$  ions as well as simple ions will be present. A further factor to be considered is the ready formation of insoluble basic compounds. In solutions which do not contain chloride (e.g., sulfate or nitrate solutions), corrosion rates are usually lower and the electrode potential is more steady over a wide range of conditions.

Gatty and Spooner consider that the rate of corrosion is probably determined by the rate at which metal ions can escape through pores in the protective oxide film, and this is supported by the results of

experiments on the anodic and cathodic polarization of copper.

One of the potential–pH equilibrium diagrams devised by Pourbaix<sup>17</sup> relating to the Cu–H<sub>2</sub>O system is shown in **Figure 1**. Such diagrams are of considerable assistance in discussing many problems associated with the chemistry, electrochemistry, electrodeposition, and corrosion of copper. It must be pointed out that the thermodynamic approach on which these are based has limitations, the most important being that, although predictions can be made about the possibility of a given reaction proceeding in certain circumstances, no information can be gained about the rate at which it will proceed.

A similar method of representing the behavior of copper in dilute aqueous solutions by means of corrosion-current/pH diagrams has been given by Rubinic and Markovic.<sup>18</sup> A study of the behavior of copper when anodically polarized has been made by

Hickling and Taylor<sup>19</sup> and, more recently, by Kuksina *et al.*<sup>20</sup> using electrochemical methods which record the variation of potential with the Faradaic charge passed. In alkaline solutions, the main stages of polarization have been found to be (1) the charging of the double layer, and (2) the formation of a film of cuprous oxide which was almost at once oxidized to cupric oxide. Mayer and Muller<sup>21</sup> report evidence that this converts to Cu<sub>2</sub>O<sub>3</sub> at potentials above –25 mV versus Hg/HgO in 1 M KOH. However, in 0.1 M NaOH,<sup>20</sup> the Cu<sub>2</sub>O film was found to be around four molecules thick when oxygen evolution first commenced. In buffer solutions of decreasing pH, the formation of sparingly soluble salts preceded or accompanied the formation of the oxide film. In acid solutions yielding soluble copper salts, no passivity developed, the anodic process being merely dissolution of copper. In nitrate solutions, the cathodic process has a significant effect on the

**Figure 1** Potential–pH equilibrium for the system copper–water at 25 °C.

anodic dissolution of copper. Low-frequency AC polarization techniques have shown<sup>22</sup> that  $\text{OH}^-$  ions adsorbed during the cathodic half-cycle facilitate copper dissolution in the anodic half-cycle through the production of an insoluble hydroxide layer. Other workers have also studied the anodic behavior of copper or copper alloys in alkaline<sup>23</sup> and in acid<sup>24,25</sup> solutions, using both static conditions and turbulent conditions, such as those generated by rotating cylinder electrodes<sup>26</sup> and the presence of light has been found to have an influence on the electrochemistry.<sup>21</sup> For instance, in Cu–Al–Sn anodically polarized in sodium sulfate solution,<sup>27</sup> an enrichment of the passive film with aluminum oxide can be detected as the photocurrent spectrum changes from a ‘copper-type’ to an ‘aluminum-type’ with time.

The excellent corrosion resistance of cupronickel alloys is related to the formation of a particularly effective protective film of corrosion products in the early stages of exposure. A number of studies have been carried out involving a wide range of analytical techniques.<sup>28</sup> The film formed is dark brown in color and there is general agreement that it contains an inner layer of  $\text{Cu}_2\text{O}$  which is enriched with nickel and iron. Recent electrochemical studies<sup>29</sup> have identified that over this layer, a thin outer layer of  $\text{CuO}$  develops and an increasing nickel content in the alloy produces a decrease in the overall corrosion rate. The corrosion rate also falls as the chloride ion concentration rises above 0.3 M due to an enhanced formation of the passive  $\text{Cu}_2\text{O}$  film.<sup>30</sup> On this subject, in a seawater context, see [Section 3.07.3.5](#).

### 3.07.3 Corrosive Environments Experienced

Copper and its alloys have a very diverse range of properties and their application exposes them to many types of environment. Artifacts dating back thousands of years are testimony to the resilience of copper alloys to atmospheric corrosion, waters, and soils. Also, they have been recognized for marine use for several decades and are still selected even though other noncopper alloy systems have been developed in the interim. The release of copper ions and the cuprous oxide film have antifouling properties and, in addition, recent work has proved their antimicrobial properties; investigations into the mechanisms for these beneficial effects are ongoing, as are their development into new applications. More traditional applications requiring corrosion resistance of copper

alloys involve roofing, plumbing, naval and commercial shipping, and desalination plant. The level of corrosion and corrosion mechanisms occurring in different environments depend on the alloy group chosen and can vary from mildly resistant to highly resistant. Various corrosion mechanisms exist and these have been found to be related to the type of alloy and to the environment to which it is exposed. The following sections give details of the effects seen in a range of different corrosive environments experienced.

#### 3.07.3.1 Atmospheric Corrosion

Copper has a high degree of resistance to atmospheric corrosion and is widely used for roofing sheets, flashings, gutters, and conductor wires as well as for statues and plaques. The corrosion resistance of copper and its alloys is due to the development of protective layers of corrosion products, which act to reduce the subsequent rate of attack. The formation, in course of time, of the typical green ‘patina’ gives copper roofs a pleasing appearance; indeed, methods are used to produce it artificially or to accelerate its formation.<sup>31</sup> The nature of the corrosion products formed on copper exposed to the atmosphere has been exhaustively studied by Vernon and Whitby.<sup>31–33</sup> A comprehensive review of the literature on atmospheric corrosion including copper and copper alloys up to 1995 has been produced by Dechema<sup>34</sup> It has been found that in the early periods of exposure, the corrosion deposit contains sulfide, oxide, and soot. By the action of sulfuric acid and by the oxidation of sulfide, copper sulfate is formed and this hydrolyzes and forms a coherent and adherent basic form of this compound. Initially, this approximates to  $\text{CuSO}_4\text{--Cu}(\text{OH})_2$  but it gradually increases in basicity until after 70 years or so it becomes  $\text{CuSO}_4\text{--}3\text{Cu}(\text{OH})_2$  and is identical with the mineral brochantite. In some cases, small quantities of basic carbonate,  $\text{CuCO}_3\text{--Cu}(\text{OH})_2$  (malachite), are also present, and, near the sea coast, basic chloride  $\text{CuCl}_2\text{--}3\text{Cu}(\text{OH})_2$  (atacamite) is produced. However, even very near the sea coast, sulfate usually predominates over chloride.

In laboratory tests, Vernon<sup>33</sup> showed that the relative humidity and the presence of sulfur dioxide have a profound effect on the rate of corrosion of copper, as they do with many other metals. He found that when the relative humidity was less than 63%, there was little attack even in the presence of much sulfur dioxide, but when the relative humidity was raised to

75%, corrosion became severe and increased with the concentration of sulfur dioxide present. By exposing specimens to the atmosphere at different times of the year, Vernon found that the rate of attack on copper was determined by the conditions prevailing at the time of first exposure. For specimens first exposed in winter, there was a linear relationship between increase in weight and time of exposure, indicating that the layer of corrosion product formed under these conditions was nonprotective. For specimens first exposed in summer, the square of the increase in weight was proportional to the time of exposure. This indicated that the coating formed in summer (when the atmospheric pollution was relatively low) was protective. It was found that the parabolic law holds when the corrosion product layer obstructs the access of the corrosive agent to the metal, the rate of attack then being inversely proportional to the thickness of the layer. It was apparent that the protective character of the layer persisted through subsequent periods when the pollution was relatively high.

Copper tarnishes rapidly when exposed to atmospheres containing hydrogen sulfide. Atmospheric corrosion tests on copper and several copper alloys were carried out by Hudson<sup>35</sup> at a number of sites in the United Kingdom. Corrosion damage was assessed by one or more of the following methods: gain in weight, loss of weight after cleaning, loss of electrical conductivity, and loss of tensile strength. Hudson found that the resistance to atmospheric corrosion was high and that the rate of attack tended to decrease with time of exposure. Little difference was found between the behavior of arsenical copper and high-conductivity copper, and most of the alloys

tested behaved very similarly except for the brasses, which deteriorated more rapidly owing to dezincification (see [Section 3.07.3.3.2](#)). Several series of atmospheric exposure tests have been carried out since Hudson's work, and the loss in weight data obtained in six of the most important investigations are summarized in [Table 5](#). In all cases, losses in tensile strength were also determined, and the results from the two methods were, in general, in good agreement. However, for alloys suffering selective attack (such as with the dezincification of brasses) change in mechanical properties usually provided a more reliable indication of deterioration than weight loss. Some other findings common to all the tests were that (1) corrosion rates decreased with time, (2) least attack occurred at rural sites and most in urban and industrial atmospheres, (3) corrosion was uniform, and (4) with a few exceptions, there was no significant pitting.

Tracy *et al.*<sup>36</sup> exposed specimens of 11 different grades of copper in the form of sheet and wire to rural, marine, and industrial atmospheres in the United States for periods up to 20 years. The differences in the behavior of the materials were small and of little, if any, practical significance. Very similar results for various types of copper were found by Mattsson and Holm<sup>37</sup> in Sweden and Scholes and Jacob<sup>38</sup> in the United Kingdom (see [Table 5](#)).

[Table 5](#) gives the results of tests on copper alloys by Tracy,<sup>36</sup> Thompson,<sup>40</sup> and Mattson and Holm,<sup>37</sup> Scholes and Jacob<sup>38</sup> and, more recently, Morcillo<sup>39</sup> together with their co-workers. The tests of Tracy and Scholes were for periods up to 20 years; in the work of Thompson and Mattson, specimens were

**Table 5** Atmospheric corrosion tests on copper and copper alloys

	No. of types of copper	No. of different alloys	No. of sites	Period of exposure (years)	Average rates of attack from weight losses ( $\text{mm year}^{-1} \times 10^4$ )		
					Rural sites	Marine sites	Urban/Industrial sites
Tracy, Thompson, and Freeman <sup>36</sup>	11	—	4	20	5.6–4.3	6.9–9.4	8.6–12
Tracy <sup>43</sup>	2	9	7	20	0.5–7.6	1.3–23 <sup>a</sup>	13–30 <sup>a</sup>

<sup>a</sup>Rates of attack for high tensile brass were  $(45\text{--}115) \times 10^{-4} \text{ mm year}^{-1}$ .

removed after 2 and 7 years and further specimens were removed after 16 years.<sup>41</sup> The average penetration during the 16-year period was found to be about the same as during the first 7 years, but considerably lower than during the initial 2 years. The materials tested included brass, nickel-silvers, cupronickels, copper-beryllium alloys, and various bronzes. Recent studies have involved the investigation of seasonal effects of industrial pollutants ( $\text{NO}_x$ ) and comparison of rural and marine locations in South America.<sup>42</sup>

In the tests described by Tracy,<sup>43</sup> a high-tensile brass suffered severe dezincification (see Table 5). The loss in tensile strength for this material was 100% and, for a non-arsenical 70–30 brass, 54%; no other material lost more than 23% during 20 years' exposure. In Mattsson and Holm's tests, the highest corrosion rates were also shown by some of the brasses. Dezincification caused losses of tensile strength of up to 32% for a  $\beta$  brass and up to 12% for some of the  $\alpha$ - $\beta$  brasses; no other materials lost more than 5% in 7 years. Dezincification also occurred, though to a lesser degree, in the  $\alpha$  brasses tested, even in a material with as high a copper content as 92%. Incorporation of arsenic in the  $\alpha$  brasses consistently prevented dezincification only in marine atmospheres.

In Thompson's reported work, the alloy showing the lowest rate of attack at all sites was a bronze containing 7Al–2Si. Relatively high corrosion rates were shown by Cu–5Sn–0.2P at a marine site and Cu–2.5Co–0.5Be in an industrial environment. The beryllium–copper alloys were the only materials to show measurable pitting, the deepest attack being 0.6 mm after 7 years. In Scholes and Jacob's tests pitting, intergranular (or transgranular) penetration, or selective attack occurred on some alloys. The maximum depth of attack exceeded 0.2 mm in 20 years on 6 of the 21 materials (three brasses, two nickel silvers, and Cu–20Ni–20Mn), but exceeded 0.5 mm in 20 years only on Cu–20Ni–20Mn and 60/40 brass. These two latter alloys lost up to 73% and 13% respectively of their tensile strength; no other alloys lost more than 10% in 20 years.

The work of Ramos *et al.*<sup>42</sup> has demonstrated a clear correlation between seasonal increases in  $\text{SO}_2$  and  $\text{NO}_x$  concentrations in urban atmospheres with higher corrosion rates and the presence of sulfates in the corrosion products. This broadly agreed with a previous study of comparative weight gains of copper over a 2-year period at 39 sites spread across Europe,<sup>44</sup> where a clear correlation was found between weight gain and  $\text{SO}_2$  content of the environment, although attempts to find mathematical

correlations of weight increase with other atmospheric species was not found to be possible. However, other works report that the corrosion of copper by sulfur dioxide is measurably accelerated by the presence of  $\text{NO}_2$ <sup>45</sup> or ozone.<sup>46</sup> The recent study conducted in South America, which involved the comparison of 21 unpolluted sites with 45 marine locations, showed that there is a threshold chloride concentration of  $20 \text{ mg m}^{-2} \text{ day}^{-1}$  in the environment above which the corrosion rate intensifies. Other recent studies have involved comparing the effects of different types of climates throughout four continents.<sup>47</sup>

From the work described and other investigations,<sup>48</sup> it is evident that copper and most copper alloys are highly resistant to atmospheric corrosion. The reported results indicate that copper itself is as good as, or better than, any of the alloys with regard to atmospheric corrosion. Some of the brasses are liable to suffer rather severe dezincification and it is unwise to expose these to the more corrosive atmospheres without applying some protection.

When unusually rapid corrosion of copper and its alloys occurs during atmospheric exposure, it is likely to be for one of the following reasons:

1. Extreme local pollution by products of combustion.
2. Bad design or construction, for example, the presence of crevices where moisture may lodge for long periods, including, for instance, coiled wire.<sup>49</sup>
3. Constant dripping of rain water contaminated by atmospheric pollution (e.g., from near-by chimney stacks) or by organic acids from lichens, etc.
4. Corrosion fatigue due to inadequate allowance for expansion and contraction with consequent buckling as the temperature fluctuates.

Most of these disorders can be avoided by attention to design.<sup>50</sup>

The discussions in recent years of the possibility of pollution occurring as a result of released copper due to atmospheric corrosion have resulted in studies of runoff from roofs and facades by several workers.<sup>51–54</sup> A number of research results have been published by the Royal Institute of Technology, Stockholm, Sweden<sup>55–61</sup> and the EMPA laboratories, Switzerland. It has been found that, after a short initiation period, the runoff rate of copper per year is constant over a long time.<sup>55,56,58,62</sup> This makes it possible to model the copper runoff rate,  $R$ ,<sup>57</sup> based on  $\text{SO}_2$  concentration, the pH of the rainwater, and its quantity. The roof surface angle of inclination  $\theta$  has

also been taken into account,<sup>61</sup> according to the following equation:

$$R = (0.37[\text{SO}_2]^{0.5} + 0.95[\text{Rain}]10^{-0.62\text{pH}}) \frac{(\cos \Theta)}{(\cos 45^\circ)} \quad [5]$$

The seasonal variation of copper corrosion rate and the runoff rate have also been studied.<sup>60</sup>

Some workers note that the released metal from the corrosion reaction is in ionic form directly on the roof and the environmental impact of these released ions has been determined. Other workers state that the run-off is mainly in particulate form. However, the interaction with solid surfaces in the near vicinity of buildings has been looked at together with the changes of transport which occur from the source to the end product. Investigations of reactivity have been made toward various natural and manmade surfaces, such as different soil systems, limestone, and concrete. The results illustrate that, for scenarios where copper ions come in extensive contact with solid surfaces, a large fraction of released copper is retained in the immediate vicinity of the building.<sup>56</sup> The potential ecotoxic effects from released copper have also been investigated. Copper biosensor testing with a bacteria and growth inhibition testing with green algae have been used. The runoff water directly after release was found to cause significant reduction of the green algae growth rate, indicating that the copper is bioavailable. However, it was found that contact with solid surfaces effectively reduces this bioavailable copper.

The fate of released copper in runoff has also been studied in the United States.<sup>62–64</sup> The results obtained also show that the bioavailable copper fraction is low after contact with solid surfaces.

Sundberg<sup>62</sup> followed the runoff from a new copper roof for 3.5 years. A relatively stable runoff rate per year was found after 0.5 years. The result was

compared with the runoff from a roof prepatinated 40 years ago, which was found to have a copper runoff rate which was 10% lower.

### 3.07.3.2 Soil Corrosion

Several extensive series of soil-corrosion tests have been carried out by the National Bureau of Standards in the United States, and the results summarized by Romanoff.<sup>65</sup> In one series, 2 types of copper and 10 copper alloys were exposed in 14 different soils for periods up to 14 years. The results for the copper specimens are summarized in Table 6.

The behavior of the phosphorus-deoxidized and tough-pitch coppers was, in general, very similar. At the less corrosive sites, with a few exceptions, copper was the best material. Most of the alloys lost weight ranging up to twice that of copper, with maximum depths of attack up to three times greater. At the other sites, although the coppers were usually rather better than the alloys, some of the alloys were occasionally superior.

The three most corrosive sites were rifle peat (pH 2.6), cinders (pH 7.6), and tidal marsh (pH 6–9). Corrosion of some of the alloys was particularly severe in the cinders. The behavior of the brasses tested, particularly those high in zinc, was rather different from that of the other materials. In most cases dezincification occurred and the brasses were the worst behaved materials; in the cinders, for instance, several brass specimens were completely destroyed by dezincification. However, in some of the soils rich in sulfides, the brasses were the best materials.

The British NonFerrous Metals Research Association carried out two series of tests, the results of which have been given by Gilbert<sup>66</sup> and Gilbert and Porter<sup>67</sup>; these are summarized in Table 6. In the first series,<sup>66</sup> tough pitch copper tubes were exposed at

**Table 6** Soil-corrosion tests on copper by National Bureau of Standards and British Nonferrous Metals Research Association (BNFMRA)

	<i>Period of exposure (years)</i>	<i>Average rate of attack from loss in weight (mm year<sup>-1</sup> × 10<sup>-4</sup>)</i>	<i>Maximum rate of pitting (mm year<sup>-1</sup>)</i>
BNFMRA first series five least corrosive soils	10	0.5–2.5	Nil
BNFMRA second series four least corrosive soils	5	5.0–25	0.140
Nat. Bur. Standards nine least corrosive soils	14	4.0–25	0.043
Nat. Bur. Standards two next most corrosive soils	14	23–130	0.033
BNFMRA first series acid clay and acid peat	10	53–66	0.046
BNFMRA second series cinders	5	66	0.32
Nat. Bur. Standards three most corrosive soils: rifle peat, cinders, tidal marsh	14	160–355	0.115

seven sites for periods of up to 10 years. The two most corrosive soils were a wet acid peat (pH 4.2) and a moist acid clay (pH 4.6). In these two soils, there was no evidence that the rate of corrosion was decreasing with duration of exposure. In the second series,<sup>67</sup> phosphorus deoxidized copper tube and sheet were exposed at five sites for 5 years. Severe corrosion occurred only in cinders (pH 7.1). In these tests, sulfides were found in the corrosion products on some specimens and the presence of sulfate-reducing bacteria at some sites was proved. However, it was not clear to what extent the activity of these bacteria was a factor accelerating the corrosion of copper.

Cinders and acid peaty soils are obviously among the soils most corrosive toward copper. There is, however, no direct relationship between the rate of corrosion and any single feature of the soil composition or constitution.<sup>68</sup> For instance, in the American tests, corrosion in several soils with either low pH or high conductivity was not particularly severe, while the British tests show that chloride or sulfate contents are not necessarily harmful. The latter tests showed that bare copper can safely be buried in a wide range of soils without fear of excessive corrosion. Experience of the behavior of copper water service pipes, which are used widely, confirms this. Difficulties are generally confined to 'made-up' ground containing cinders, etc. and a few other aggressive soils, and in these circumstances it is necessary to apply protection such as bitumen-impregnated wrappings or plastic coatings. Tin coatings cannot be recommended as experience shows that accelerated attack is liable to occur at pores and scratches in the coating, leading to premature failure. Copper water pipes have been known to fail by the action of stray electric currents, but this is not a common occurrence.

There is agreement between the soil-corrosion tests carried out by National Bureau of Standards and practical experience of the behavior of hot-pressed brass fittings used for joining copper water service pipes. These duplex-structure brass fittings are liable to suffer attack by dezincification in many soils in which copper behaves satisfactorily, and, for burial underground, fittings of copper, gunmetal, or dezincification-resistant brass are to be preferred. In general, it may be said that, unless there is some special reason for using a copper alloy, it is preferable to choose copper for applications involving subterranean service. A comparison of the corrosion produced through the influence of possible ionic species present around buried copper has shown<sup>69</sup> that the major damage is caused by chloride ions.

Ammonium and sulfide species appear to be relatively benign. The corrosion products which result are cuprite and malachite, the latter being favored for soils with higher water content.<sup>70</sup>

### **3.07.3.3 Corrosion in Natural Waters**

Copper and copper alloy pipes and tubes are used in large quantities both for conveying fresh and salt water and in condensers and heat exchangers where fresh or salt water is used for cooling. Pumps, screens, valves, and other ancillary equipment may also be largely constructed of copper alloys. Large tonnages of these materials are therefore used on offshore structures, multistage flash desalination plants, power stations, on board ships, in sugar factories, and in oil refineries, as well as in hot and cold water circuits and heating and cooling systems in hospitals, factories, hotels, and homes.

Corrosion problems that arise frequently are discussed under separate headings, depending on whether the environment is seawater or freshwater. In fact, there is no sharp dividing line between these environments, since some harbor, estuarine, and brackish well waters are mixtures of seawater and freshwater and are often variable in composition. Corrosion has been found to occur in all these media, particularly in seawater, but this is more frequently seen as a result of poor design or operation than as a result of lack of materials suitable for the application. This section will deal with the types of corrosion which can be seen in all types of natural water; seawater, brackish water, or freshwater. Separate sections will follow which deal with corrosion types seen almost entirely solely in freshwater and with the behavior of copper alloys specifically in seawater.

#### **3.07.3.3.1 Impingement attack**

Copper alloys have good corrosion resistance under moderate fluid flow rates. However, above a certain flow velocity, called the breakaway velocity, the shear stress of the liquid on the alloy protective surface film is sufficient to damage it and much higher corrosion rates occur. This phenomenon is called impingement attack or erosion-corrosion. Therefore, tube and piping systems are designed to operate satisfactorily up to a maximum velocity and it is important that this is not exceeded in service. Breakaway velocity can be influenced by many factors, including the alloy being used, the resilience of the surface film, the geometry of the product and system, the corrosive nature of the

fluid being handled, pollution, solids (e.g., sand in seawater), and turbulence.<sup>71</sup>

Copper tubes have been found to suffer from impingement attack in systems where the speed of water flow is unusually high. The phenomenon has been discovered to be dependent in some degree on the quality of the water, for instance where no protective scale is able to form, for example, in a soft water containing appreciable quantities of free carbon dioxide.<sup>72</sup> Impingement attack is most often seen downstream of poorly installed fittings or sharp bends in pipework systems. Such obstructions to flow and sharp changes in direction where the speed of the water is high can lead to eddy currents concentrating the flow on specific parts of the tube, the creation of bubbles at areas of low pressure (which subsequently collapse), and the streaming of particulate matter. The latter can act alone or in concert to remove any protective scale that has formed on the copper surface, thus exposing the metal to further corrosion and subsequent removal of corrosion product. In such a way, severe metal loss can occur, leading eventually to failure of the tube. Impingement attack is characterized by areas of bright metal and horseshoe-shaped undercut areas, their direction being as though the horse was walking upstream. In the middle of such undercut areas, there may be islands of bright metal or metal still retaining some protective corrosion product. An example of this phenomenon is shown in [Figure 2](#). Ball valve seatings may also suffer an erosive type of attack. The corrosion of ball valves, including the effect when the water is chlorinated, has been studied by several workers.<sup>73</sup> Avoidance of impingement attack is usually achieved by reducing the flow velocities by one

**Figure 2** Photograph showing typical impingement attack caused by eddy currents which were present as a result of burrs on the internal wall. The tube type is 15 mm diameter copper tube to EN 1057, R250 (half-hard condition).

or a combination of the following: reducing the pump output, increasing the pipe size, modification of the change of direction to one which is less abrupt, opening partially closed valves, etc. The maximum flow velocity quoted in European Standard EN806 part 3 is  $2.0 \text{ m s}^{-1}$  for header, riser, and floor service pipes and  $4.0 \text{ m s}^{-1}$  for (replaceable) connection pipes to one fitting. The Swedish Building Standard 2522 recommends a reduction in velocity as the design operating water temperature increases viz,  $2 \text{ m s}^{-1}$  at  $10^\circ\text{C}$ ,  $1.5 \text{ m s}^{-1}$  at  $50^\circ\text{C}$ ,  $1.3 \text{ m s}^{-1}$  at  $70^\circ\text{C}$ , and  $1.0 \text{ m s}^{-1}$  at  $90^\circ\text{C}$ .

The actual velocity at which impingement commences depends on the fluid and varies from alloy to alloy.<sup>74</sup> In general, the nickel aluminum bronzes and copper–nickel alloys have the highest velocity tolerances in seawater and are somewhat better than gunmetals, brasses and tin bronzes<sup>75</sup> (see [Table 7](#) and [Section 3.07.3.5](#)). The cupronickel 90–10 and 70–30 alloys are commonly used for seawater condensers, heat exchangers, and pipework in naval vessels as well as merchant shipping. For tube sizes used in heat exchangers and condensers, the velocity is limited to  $\sim 2\text{--}2.5 \text{ m s}^{-1}$ . For seawater pipework of internal diameter 100 mm and with bends of long radius, the recommended maximum seawater flow velocities are  $3.5 \text{ m s}^{-1}$  for the 90–10 alloy and  $4 \text{ m s}^{-1}$  for the 70–30 alloy<sup>76</sup>. This has worked well in practice although it is now believed to be a little on the conservative side.<sup>77,78</sup> Areas causing high turbulence such as bends with tight radii, partially throttled valves, and partial obstructions need to be avoided.

Other cupronickel alloys have been developed and have been found to offer even better resistance to impingement attack. In particular, a 16.5% Ni–0.5% Cr alloy first developed by INCO in the 1970s has a much higher, critical shear stress than the 70–30 alloy.<sup>12</sup> Also a 2% Mn–2% Fe–30% Ni alloy, developed for extra impingement resistance in situations where entrained sand is present in seawater, is now successfully used in the more demanding areas of desalination plants.<sup>9</sup>

Gunmetals and aluminum bronzes have good resistance to impingement attack but these alloys are not normally used for heat exchange tubing, the former because they are casting alloys and the latter because it may pit in quiescent conditions. However, both groups are used for components such as pumps and valve bodies. The nickel aluminum bronze alloy is used for propellers and pump components as it has excellent resistance to cavitation compared to many other copper based alloys.

**Table 7** Comparative results showing corrosion and erosion/corrosion performance of a number of copper alloys<sup>a</sup>

<i>Alloy</i>	<i>General corrosion rate (mm year<sup>-1</sup>)<sup>b</sup></i>	<i>Crevice corrosion rate (mm year<sup>-1</sup>)<sup>b</sup></i>	<i>Minimum flow rate to produce erosion/corrosion (m s<sup>-1</sup>)<sup>c</sup></i>

<sup>a</sup>Due to difficulties of achieving consistent results for tests in seawater, data should be used for comparing relative performance rather than being taken as absolute.<sup>75</sup>

<sup>b</sup>The figures for general corrosion rate and crevice corrosion rate were determined using samples fully immersed beneath rafts in Langstone Harbour, Portsmouth, UK, for 1 year.<sup>75</sup>

<sup>c</sup>The corrosion/erosion resistance tests were carried out using the following method (known as the Brownsdon and Bannister method): the specimens were fully immersed in natural sea water and supported at 60 °C to a submerged jet, 0.4 mm diameter placed 1–2 mm away, through which air was forced at high velocity. From the minimum air jet velocity required to produce corrosion/erosion in a fourteen-day test, the minimum sea water velocity required to produce corrosion/erosion under service conditions was estimated on the basis of known service behavior of some of the materials.

A number of studies have evaluated the impingement resistance for marine condensers and piping involving several types of test apparatus, including rotating discs, rotating spindles, model condensers, multivelocity jet tests, and jet impingement tests.<sup>79</sup> This work has proved reliable in ranking materials as a function of impingement resistance and has been an important factor in the development of alloys resistant to impingement attack.

Experience has shown that for intermittent flow (as might be the case of firewater systems used on offshore platforms which are tested periodically), short-term high velocities in the order of 7–15 m s<sup>-1</sup> for cupronickels are not detrimental. Also open geometries need not have the velocity restrictions of pipe and tubing; for example, 90–10 cupronickel has been successfully used on ship hulls operating at 24 knots (12 m s<sup>-1</sup>) with little thinning experienced.<sup>9</sup>

### 3.07.3.3.2 Dezincification of brasses

Historically, the most common dealloying phenomenon seen in copper alloys has been the dezincification of brasses. In recent years, the development of dezincification-resistant brasses and a greater understanding of the required conditions under which dezincification manifests itself have lessened its occurrence, but it retains a high degree of scientific interest. Dezincification is characterized by regions of the brass becoming replaced by a porous mass of copper which, though retaining the shape of the original article, has virtually no strength. There has long been discussion as to whether there is selective corrosion of the zinc in the brass, which leaves the copper behind, or whether complete dissolution of the brass occurs, followed by redeposition of copper. Possibly both processes occur under different circumstances.

The mechanism of dezincification of brass has been investigated and discussed by Evans,<sup>80</sup> Fink,<sup>80</sup> Lucey,<sup>81</sup> Feller,<sup>82</sup> and Heidersbach,<sup>83</sup> and is referred to in many other papers.<sup>84–92</sup> Recent extensive studies<sup>93,94</sup> which have investigated the distribution of copper isotopes and the effects of specimen rotation during testing, show that redeposition of copper is a major mechanism.

With a single-phase brass, the whole of the metal in the corroded areas is affected. Dezincification may proceed fairly uniformly over the surface, and this 'layer type' takes much longer to cause perforation than the more localized 'plug type' which more often occurs.<sup>95</sup> With a two-phase brass, the zinc-rich  $\beta$  phase is preferentially attacked and eventually the  $\alpha$  phase may be attacked as well. The zinc corrosion products which accompany dezincification may be swept away, or, in some conditions, may form voluminous deposits on the surface. These may in turn lead to blockages, for example, in fittings. In general, the rate of dezincification increases as the zinc content rises, and great care needs to be exercised in making brazed joints with copper/zinc brazing alloys, particularly if they are to be exposed to seawater. Under these conditions, a properly designed capillary joint may last for some time, but it is preferable to use corrosion-resistant jointing alloys such as silver solders<sup>96</sup>, as specified in BS EN 1044:1999.

Factors which cause increased rates of dezincification are high temperature, high chloride content of water, and low water speed.<sup>97–100</sup> Dezincification is also likely to occur preferentially beneath deposits of sand or silt on the metal surface, or in crevices where there is a low degree of aeration.

Addition of  $\sim 0.04\%$  arsenic will inhibit dezincification of  $\alpha$  brasses in most circumstances and arsenical  $\alpha$  brasses can be considered to be immune to dezincification for most practical purposes.<sup>101</sup> There are conditions of exposure in which dezincification of these materials has been observed, for example, when exposed outdoors well away from the sea<sup>37</sup> or when immersed in pure water at high temperature and pressure, but instances are rare. In other conditions, for example, in polluted seawater, corrosion can occur with copper redeposition away from the site of initial attack, but this is not truly dezincification, which, by definition, requires the metallic copper to be produced *in situ*. The work of Lucey<sup>81</sup> goes far in explaining the mechanism by which arsenic prevents dezincification in  $\alpha$  brasses

but not in  $\alpha$ – $\beta$  brasses. An interesting observation is that the presence of a small impurity content of magnesium will prevent arsenic in  $\alpha$  brass from having its usual inhibiting effect.<sup>102</sup>

The addition of antimony or phosphorus, in amounts similar to arsenic, are claimed to be also capable of preventing dezincification of  $\alpha$  brasses. However, most manufacturers use arsenic. It appears desirable to avoid using phosphorus, as Bem<sup>103</sup> has shown that this element can, in some circumstances, lead to an undesirable susceptibility to intergranular corrosion. The same can be true for arsenic additions over  $\sim 0.05\%$ .

A dezincification resistant alloy, CW602N, was first introduced in 1980. This alloy is a leaded brass with a zinc content sufficiently high to permit hot forging and extrusion in the  $\beta$  range without cracking. After hot working, a heat treatment of up to 6 h at 500 °C followed by slow cooling transforms any residual  $\beta$  phase to  $\alpha$  so that the finished component is essentially  $\alpha$  brass. Dezincification is inhibited by adding arsenic (0.02–0.15%) which protects the  $\alpha$  phase, and good machinability is assured by adding lead (1.7–2.8%). The impurities iron and manganese, which combine with arsenic, must be carefully controlled for the arsenic to be effective. A rule of thumb is that the percentage of arsenic must be greater than the combined percentage of iron and manganese to provide resistance to dezincification. There is practical evidence that the maximum limits for iron and manganese allowed in the specification (0.1% each) are too high as, at these levels, the arsenic may be rendered ineffective.

Newer studies of intergranular corrosion attack (IGA) of arsenic-containing dezincification resistant brass<sup>93,104</sup> show that there is a close relationship with the degree of precipitation of iron–arsenic compounds in the grain boundaries. The precipitates are formed during low temperature heat treatment or slow cooling after hot forging or a prior heat treatment. Sulfide corrosion and dezincification in the grain boundary appear to be the result as the arsenic is bound to impurities like iron. IGA has also been reported for aluminum brass (CW 702R) and Mazza and Torchio<sup>105</sup> have presented a laboratory test method to reveal IGA in this material. The method has also been used successfully for dezincification resistant brass<sup>104</sup> and correlation with field tests in seawater is good.

The addition of 1% tin can markedly reduce the rate of dezincification in two phase brasses, and naval

brass (61Cu–38Zn–1Sn) is attacked considerably more slowly than 60/40 brass in seawater, although there may be virtually no difference between them in most freshwaters. Some of the cast complex high-strength two-phase brasses containing tin, aluminum, iron, and manganese appear to have relatively good resistance to dezincification, but they are by no means immune to it.

Dezincification of brasses in drinking water may occur, particularly in stagnant or slowly-moving warm or hot waters relatively high in chloride and containing little carbonate hardness.<sup>106</sup> Dezincification of  $\alpha$  brasses is inhibited by the usual arsenic addition, but two-phase brasses are liable to severe attack in some waters. In such cases, dezincification-resistant brass or gunmetal fittings should be used. If copper/zinc brazing alloys are used, these may dezincify in water known to support this type of corrosion and may consequently give rise to leaks.<sup>106</sup>

#### 3.07.3.3.3 Selective attack in other alloys

Selective attack analogous to dezincification can occur in other copper alloys, particularly in aluminum bronzes and, less frequently, in tin bronzes,<sup>107</sup> cupronickels,<sup>108</sup> and other alloys. Dealuminification of aluminum bronzes has been studied extensively<sup>109</sup> and the results indicate that, while  $\alpha$ -phase alloys suffer such attack comparatively rarely, alloys of higher aluminum content can be more susceptible. The electrochemical relationships are such that preferential corrosion of the second phase is liable to occur in  $\alpha$ - $\gamma_2$  alloys, but  $\alpha$ - $\beta$  alloys are relatively resistant to attack. Retention of  $\beta$  phase is favored by rapid cooling after casting or after high temperature heat treatment, and also by incorporating manganese in the alloy. A tempering heat treatment in the temperature range of 650–740 °C has been found to hinder the occurrence of dealuminification due to the transformation of the more corrosion-prone  $\beta$  phase to a combination of  $\alpha$  phase and comparatively benign  $\kappa$  phases.<sup>110</sup>

The addition of nickel to aluminum bronze has been found useful in controlling the occurrence of the  $\gamma_2$  phase, which has a corrosion potential  $\sim 100$  mV less noble than the  $\alpha$  phase, thereby undergoing selective attack in seawater. Weill-Couly and Arnauld<sup>111</sup> have determined an empirical relationship, eqn [6] shown below, which denotes the aluminum content of nickel–aluminum bronze castings below which a resistance to dealuminification is found.

$$\text{Al} \leq 8.2 + \frac{\text{Ni}}{2} \quad [6]$$

#### 3.07.3.3.4 Deposit attack and pitting

When water speeds are low and deposits settle on the surface, pitting in copper and copper alloys is liable to occur by differential aeration effects. This is particularly so at water speeds below  $\sim 1 \text{ m s}^{-1}$ . In seawater systems, such attack may occur under dead barnacles or shellfish, the decomposing organic matter assisting the corrosion process. Pitting is most likely to occur in polluted in-shore waters, particularly when hydrogen sulfide is present. In such contaminated waters, non-protective sulfide scales are formed and these tend to stimulate attack. It has been found possible to develop a mathematical model which can be successfully used to calculate the electrode potential below which copper is immune to pitting in tap water or seawater in the temperature range 25–75 °C.<sup>112</sup> Of the 26 ionic species which have been included in the calculation,  $\text{CO}_3^{2-}$  and  $\text{SO}_4^{2-}$  were found to be the most aggressive.

#### 3.07.3.4 Corrosion in Freshwater

Freshwaters are, in general, less corrosive toward copper than is seawater and copper is widely and satisfactorily used for distributing cold and hot waters in domestic and industrial installations.<sup>113–116</sup> Copper and copper alloys are used for pipes, hot-water cylinders, ball valves, taps, fittings and heater sheaths. In condensers and heat exchangers using freshwater for cooling, tubes of 70/30 brass or Admiralty brass are usually used, and corrosion is rarely a problem. Nevertheless, the widespread use of copper and copper alloys since the early part of last century especially in domestic water systems has meant that all adverse situations have been experienced and the following are rare but notable corrosion issues. Two British Standards give guidance on the likelihood of corrosion in water distribution and storage systems and in water recirculating systems. These are BSEN 12502:2004 and BSEN14868:2005.

##### 3.07.3.4.1 Pitting

Occasionally copper water pipes fail prematurely by pitting. This a general term and is used for any failure of the pipework system leading to a leak. Pitting corrosion of copper in drinking water systems is often categorized as Type I, II, or III but other types of localized corrosion are also known. However, there may be no strict limits between Type I and Type II pits; in relatively saline tap waters, corrosion pits showing traits of both types have been found. Only through proper investigation can the cause of pitting be identified, such as in the following sections.

#### 3.07.3.4.1.1 Carbon film pitting

Carbon film pitting, also known as "Type I" pitting, has been a frequent problem. An example of this in a copper tube from a domestic water supply is shown in **Figure 3** with the corrosion products removed from the main pit. The characteristics of the pits are hemispherical cavities with large crusts of corrosion products outside. The composition of the crusts is mainly basic cupric carbonates for example, malachite. Cuprous chloride and reddish cuprous oxide crystals may be found inside the cavity. The presence of  $\text{CaCO}_3$  in the crust outside the cavity led Lucey<sup>117</sup> to propose a particular mechanism for this type of pitting. Contrary to conventional descriptions of the pitting processes, Lucey postulated that the cathodic reaction that is, the oxygen reduction, takes place at the crust of corrosion products which cover the cavity. The phenomenon was found to occur in organically pure, cold waters originating from deep wells and boreholes and was shown by Campbell<sup>118</sup> to be associated with residual films of carbon on the bore of the tubes. This carbon was caused by decomposition of residual drawing lubricant during bright (reducing atmosphere) annealing. It is therefore necessary for manufacturers to take steps to avoid these harmful residues. This type of pitting attack has been identified in many different countries<sup>119</sup> and may be assisted by iron-rich precipitates which can be present at the grain boundaries.<sup>120,121</sup> There is evidence that it could be inhibited by the presence of organic species in the water.<sup>122</sup>

This evidence has been corroborated in the United Kingdom by Campbell, who found failures due to this effect were confined to certain districts that is, supply waters. He showed that for many supply waters this

**Figure 3** Photograph showing carbon film pitting on a copper tube.

pitting cannot proceed even in tubes containing carbonaceous cathodic films. He proposed that this is most probably due to the presence of small amounts of a naturally-occurring inhibitor in the water, probably an organic colloidal material, which stifles pitting of copper. Pipe failures therefore only occur in waters which contain little or none of this inhibitor.

Pitting problems also occasionally occur in copper water cylinders<sup>123</sup> and, as a result of a study of this problem, Lucey<sup>117</sup> has made suggestions about the mechanism of pitting of copper in potable water supplies. Several suggested methods of avoiding pitting failures in copper cold-water tubes have been evaluated.<sup>124–126</sup>

#### 3.07.3.4.1.2 Hot soft water pitting and Type II pitting

In hot water pipes, failures sometimes occur in certain areas supplied with soft waters from moorland gathering grounds. The waters concerned contain a few hundredths of a part per million of manganese, and in the course of several years' exposure, a deposit rich in manganese dioxide is laid down in the hottest parts of the system. This may cause pitting which could eventually lead to failure.

Hot-water pitting of another type, often referred to as "Type II" pitting, is sometimes experienced in soft waters having high sulfate content in relation to the carbonate hardness and a relatively low pH value and it has been described by Mattson and Fredriksson.<sup>127</sup> The crusts covering these pits are less voluminous than Type I pits, the cavities are branching and they may be almost completely filled with black cuprous oxide. The occurrence of Type II pitting is associated with waters with  $\text{pH} \leq 7$  and low carbonate contents. A successful remedy has been to increase pH, introduce carbonate dosing to give a minimum of  $70 \text{ mg HCO}_3^-$  per liter, or reduce the water temperature to less than  $60^\circ\text{C}$ .

#### 3.07.3.4.1.3 Type III pitting

This type of pitting occurs in cold soft waters with a pH above 8.0 and it is geographically localized, being mainly confined to Sweden. It is a generalized form of pitting where the pits are sparse<sup>128,129</sup>. Mattson<sup>128</sup> describes the phenomenon, noting its morphology and means of avoidance through a method involving bicarbonate dosing of the drinking water.

#### 3.07.3.4.1.4 Electrochemistry of pitting

Drogowska *et al.*<sup>130</sup> have used solutions designed to mimic natural waters containing bicarbonate and chloride ions to study the anodic oxidation of copper and onset of pitting corrosion. They have found that,

as the anodic polarization of copper increases in this environment, a porous layer of  $\text{Cu}_2\text{O}$  initially forms on the metal surface. This is found to convert to basic  $\text{CuCO}_3$  at more positive anodic potentials or in higher concentrations of  $\text{HCO}_3^-$  ions. A passivity breakdown potential is recorded at which pitting initiates, and this becomes more positive when  $\text{HCO}_3^-$  ions are present. The presence of  $\text{Cl}^-$  ions shifts the pitting potential to lower values, but the  $\text{HCO}_3^-$  ions are found to act to prevent this effect. Sulfate ions are found to have a very similar effect to chloride ions in lowering the breakdown potential<sup>131</sup> and pitting is found to be avoided if the  $\text{pH} \geq 7.4$  and the  $[\text{HCO}_3^-]/[\text{SO}_4^{2-}]$  ratio is  $\geq 1$ . The effect of increasing the solution temperature to  $60^\circ\text{C}$  is found to give improvement to the passivity of the oxide film.<sup>132</sup> Two new international standards have been produced which give guidance on corrosion prevention in water distribution and storage systems.<sup>133</sup>

#### 3.07.3.4.2 Chemical attack

Joining copper should be accomplished according to recommended practice to avoid corrosion issues. Copper pipework installations are joined using capillary attraction of solder or braze material or by mechanical means.

In the case of capillary joints, fittings, or in some cases specifically formed tube ends, are used to form an annular capillary gap into which molten solder or braze is run. Fluxes containing chlorides have to be used when soldering. The chlorides act to remove surface oxide and reduce the surface tension, allowing the solder to be drawn into the capillary gap. Excessive use of flux can lead to its retention in the pipework and attack by the chloride ions present.

This will normally take place in the first few months after installation. An example of this is shown in **Figure 4**. Over longer periods when the active elements of the flux are exhausted, the presence of residue can lead to deposit attack. In both of these cases, pitting corrosion and failure of the tube can result. Good installation practice which ensures complete removal of any flux residue by washing (as given by BS 6700:1997) will prevent this type of corrosion. Capillary joints formed using copper/phosphorus, copper/silver/phosphorus, or silver brazing alloys do not need flux and therefore cannot suffer this type of attack.

#### 3.07.3.4.3 Microbiologically influenced corrosion

Microbiologically influenced corrosion (MIC), describes a form of pitting considered to be due to the action of microbes. This form of corrosion of metals has been known for many years, for instance in the oil industry, and an early description of its occurrence with copper alloys was given by Rogers in 1948.<sup>134</sup> In some instances, MIC has been associated with soft water which is high in organic content which has been allowed to maintain temperatures in the region of  $20\text{--}30^\circ\text{C}$  under low velocity conditions. In such circumstances, the resulting warm high concentration of organic material at the bottom of horizontal tubes provides ideal conditions for MIC to take place.<sup>135</sup> Other circumstances with a different water quality have been described by Wagner *et al.*<sup>136</sup> However, the exact MIC mechanism has not been elaborated. The general view is that a region of low pH is created under a biofilm containing polysaccharides and that the organic materials present provide transport for the metal ions to the liquid phase.<sup>137</sup>

**Figure 4** Photograph showing flux attack on a soldered copper tube.

**Figure 5** Optical micrograph showing an example of the typical pit morphology found in MIC.

MIC of copper water pipes in institutional buildings has been reported in several countries. The results of research, leading to remedial measures, have been summarized by Geesey.<sup>138</sup>

An example of this type of corrosion associated with soft high organic content water is shown in **Figure 5**. Avoidance entails operating the system at correct temperatures and flow rates as well as providing water with a low organic burden and with the implementation of appropriate disinfection measures.

#### 3.07.3.4.4 Stress corrosion cracking

Stress corrosion cracking (SCC) may occur with brass fittings (see **Section 3.07.3.6.1**) due to traces of ammonia in the environment or arising from nitrates in the water. In certain rare instances, copper tubes are known to suffer SCC, an example of which is shown in **Figure 6**. In the great majority of cases of stress corrosion encountered, traces of ammonia have been found in the cracks.

#### 3.07.3.4.5 Dissolution

The corrosion of copper in contact with drinking water soon reduces to a very low rate due to the formation of stable scale. However, some waters continuously dissolve appreciable amounts of copper.<sup>139–141</sup> Factors which favor this action are waters with low pH and low total dissolved solids. Therefore, most dissolution is found in hot, soft, acid waters. Desalination plants will produce such an aggressive water and unless treated to increase its mineral content this water should not be used with copper. This type of corrosion is general and the resulting pipe wall thinning is so slight that the useful life of the pipe or component is virtually unaffected unless

**Figure 6** Photograph showing longitudinal stress corrosion cracking of a 15 mm diameter copper tube (EN 1057, R250, half-hard condition).

impingement attack occurs. A few very hard waters can also give rise to copper dissolution. Research has indicated that the difference between a scale forming water (with a resulting low copper dissolution rate) and a ‘dissolving’ hard water appears to be organic content.<sup>142</sup>

High levels of copper complexed with organic material gives the water a distinctive blue color, and is hence given the term ‘blue water corrosion.’ It tends to be confined to soft, unstable water types and, to date, appears to be confined to Australia and New Zealand. This form of dissolution has been found to be due to microorganisms<sup>143</sup> and restoring the disinfection agent (e.g., free chlorine) to its desired level will stop the effect and prevent the occurrence of further episodes.

A review of the current state of knowledge on dissolution in drinking water has been prepared by Merkel and Pehkonen.<sup>144</sup> In considering copper dissolution, this paper subdivides general copper corrosion into the subprocesses (oxidation, scale formation, and scale dissolution) enabling a better understanding of the influence of water quality parameters and operating conditions on copper release. This work also considers that research needs to be carried out to distinguish between organic components which promote or reduce the dissolution process.

Once copper has been dissolved, it may then lead to problems downstream. For instance, the dissolved copper can (1) plate out and cause galvanic corrosion on other products such as zinc-coated steel,<sup>145</sup> light alloys,<sup>146</sup> or bare steel and (2) cause blue–green staining in baths, sinks, and sometimes clothes or hair due

to the combination of copper with stearates in soaps and shampoos.

The World Health Organization (WHO) Guidelines for Drinking Water Quality 1993<sup>147</sup> notes that copper is an essential element necessary for human health and that in most parts of the world deficiency was a problem. However, it was decided that setting an upper limit for the allowable concentration was necessary. Following this guideline, many countries have regulated the maximum weekly average of drinking water to 2 mg Cu per liter. Araya *et al.*<sup>148</sup> showed that the likely taste level for copper in drinking water was 4 mg l<sup>-1</sup> or above for 95% of the population.

In deaerated conditions, for instance, in most central heating systems, little attack on copper occurs.<sup>149–151</sup> Further reference to the subject of copper in water can be found in an extensive review by Grunau.<sup>152</sup>

### 3.07.3.5 Corrosion in Seawater

Copper alloys have had an extensive history of use in a wide range of marine applications<sup>9,153</sup> due to their advantageous properties with respect to corrosion and biofouling resistance, conductivity, and ease of fabrication.

Exposure tests of various copper alloys have been carried out in natural seawater by the UK Ministry of Defence laboratories.<sup>154</sup> Weight loss measurements were used to measure general corrosion rates, crevice corrosion rates, and erosion/corrosion flow velocity limits. The results are shown in **Table 7**, although some anomalies have been reported for the data as presented<sup>75</sup>. It was found that the brasses exhibited the highest corrosion rates and the alloys most resistant to corrosion and erosion/corrosion were the cupronickels.

Regarding practical applications of copper alloys in seawater, a major example is their use for condensers and heat exchangers, which has been long established. Recent reviews have considered potential corrosion in this application, the likely causes and remediation procedures.<sup>76,155–157</sup> Specific aspects covered include the effects of surface films, the commissioning process, stagnant conditions, flow velocity, ferrous sulfate treatment, and cleaning techniques. The latter may lead to greater corrosion, though ferrous sulfate treatment can offset the effect. Chlorination can cause increased attack in some circumstances, aluminum brass being more susceptible to attack than cupronickels. The presence of sulfide

contamination causes serious corrosion if polluted and aerated conditions alternate, or if oxygen and sulfide are simultaneously present.

Corrosion of condenser tubes was a problem of great magnitude during the first quarter of the twentieth century. In those times, 70–30 brass condenser tubes failed by dezincification and Admiralty brass (70Cu–29Zn–1Sn) was brought into use. This proved little better, but some time later the addition of arsenic was found to inhibit dezincification. Failures of Admiralty brass by impingement attack became a serious problem, particularly as cooling water speeds increased with the development of the steam turbine. The introduction of alloys resistant to impingement attack was a great step forward and immediately reduced the incidences of failure. A history of condenser tubes up to 1950 has been published by Gilbert.<sup>158</sup>

The alloys most commonly employed today are cupronickels,<sup>159</sup> containing appropriate iron and manganese levels and aluminum brass (76Cu–22Zn–2Al–0.04As). Three cupronickel alloys are in widespread use and these are: (1) 30Ni–0.7Fe–0.7Mn, (2) 30Ni–2Fe–2Mn, and (3) 10Ni–1.5Fe–1 Mn. These materials are extensively and successfully applied in ships, power stations, oil refineries, desalination plants, etc., in condensers and heat exchangers, with limitations on water flow velocities, sometimes with much entrained air present. At the highest water flow velocities, there is a rather greater factor of safety with 70–30 cupronickel. The 30Ni–0.7Fe–0.7Mn variant is usually to be preferred under most polluted water conditions.

A number of studies have been carried out on the reasons for the high seawater corrosion resistance of cupronickels. In 70–30, a nickel-rich zone is formed in the oxide layer at the metal surface.<sup>160</sup> This acts to anodically protect the matrix from further corrosion. If the film develops defects, which may be caused by prior deformation of the metal,<sup>161</sup> then corrosion initially accelerates in those areas, but quickly diminishes, resulting in a smooth overall surface.

The occasional failures which still occur in condenser tubes are usually due to one (or sometimes several) of the following factors:

1. Localized attack or pitting in badly contaminated waters.
2. Pitting under decaying barnacles, shell fish, or other deposits.
3. Impingement attack due to high local water velocities, e.g., at partial obstructions in a tube such as barnacles or *Hydra*.

4. Erosion due to sand or other abrasive particles suspended in the water.
5. Use of tubes of the wrong alloy, or of incorrect composition or which contain manufacturing defects.
6. Poor welding techniques causing welds to protrude into the flow.

The material most commonly used when suspended abrasive matter is a problem is the 30% Ni alloy containing 2% each of Fe and Mn.<sup>156,157</sup>

A difficult condenser-tube corrosion problem arises from the use of polluted cooling waters from harbors and estuaries, which may be severely contaminated, particularly when warmer climates are involved.<sup>162</sup> Many condenser-tube materials are liable to suffer corrosion in these circumstances, and the choice of materials is made difficult by the fact that different orders of merit apply at different locations and even at the same location at different times. The state of the water when the tubes are commissioned and first enter service, which influences the type of surface film formed, may well determine whether or not a satisfactory service life will be obtained.<sup>159,163</sup> Full salinity seawater, free from sulfides, is reported to be the most effective passivating medium<sup>162</sup> although the 14–60 days which this takes to complete may put it at a lower ranking than other methods, particularly those involving dosing with ferrous sulfate<sup>76</sup>.

In power plants, the condenser tubes must be able to withstand corrosive cooling waters and complex boiler water treatments. Also, the use of recirculating water can cause dissolved salts to concentrate between twice and eight times the initial concentration, making the water significantly more aggressive.<sup>164</sup> Corrosion of power-station condenser tubes by polluted waters was at one time particularly troublesome in Japan. Improved results have been reported using tin brasses or special tin bronzes.<sup>165</sup> Elsewhere, pretreatments have been investigated with mixed success<sup>76,166</sup> and sodium dimethyldithiocarbamate is reported to give protective films which will withstand the action of polluted waters<sup>167</sup> and has had some naval use.<sup>76</sup>

Methods of maintaining tube cleanliness include chlorination and mechanical methods such as water lancing and the use of the Taprogge system of circulating sponge-rubber balls.<sup>157</sup> Hot acid is now not environmentally acceptable and the use of commercial descaling agents invariably results in the near complete loss of the passive surface layers on the material.<sup>168</sup> Thus, it is recommended that, after

their use, a period of 3 weeks or more should be imposed during which natural seawater is allowed to flow through the system to restore passivity.

Condenser tube-plates of naval brass usually undergo some dezincification in seawater service, but this is normally not serious in view of the thickness of the metal involved. Use has been made of tube-plates of more resistant materials such as aluminum bronze, or cupronickel. Plates that are too large to be rolled in one piece can be fabricated by welding together two or more items. In some special applications, the tubes are fusion welded or explosively welded to the tube plates. Fusion welding operations are rather more difficult with brasses than with other copper alloys due to the evolution of zinc fume during the process.

Condenser water-boxes were at one time made of unprotected (or poorly protected) cast iron and these afforded a measure of cathodic protection to the tube plates and tube ends. This beneficial effect has been lost with the general adoption of water-boxes which are completely coated with rubber or some other impervious layer, or which are made from resistant materials such as gunmetal, aluminum-bronze, or cupronickel. Steel water-boxes which are clad with cupronickel are also used. To prevent attack on tube-plates and tube-ends in these circumstances, either a suitable applied-current cathodic protection system can be applied or sacrificial soft-iron or mild-steel anodes can be installed, the required protection voltage being fairly low (50 mV minimum).<sup>169</sup> Ferrous wastage plates have the additional advantage that the iron corrosion products introduced into the cooling water assist in the development of good protective films throughout the length of the tubes. This is particularly important in the case of aluminum-brass tubes; indeed, with such tubes it may be desirable, as an additional preventative measure, to add a suitable soluble iron salt (such as ferrous sulfate) regularly to the cooling water.

As it has become increasingly necessary to supplement natural sources of freshwater in various parts of the world, processes for producing freshwater from seawater have been intensively studied. Distillation is one method widely used and, during recent years, large numbers of multistage flash-distillation plants have been installed in various countries particularly in the Middle East. Many of the larger flash-distillation units are capable of producing several millions of gallons of freshwater per day. In these plants, seawater passes through horizontally disposed tubes and steam, which is 'flashed' from the brine, condenses

on the outside. In some parts of the plant, the conditions are similar to those in steam condensers, but in other parts the seawater has been treated to remove dissolved gases and is at much higher temperatures. Copper alloy tubes are used in large numbers for the heat exchange units in this type of desalination plant,<sup>170,171</sup> these being mainly aluminum-brass and the various cupronickel alloys.

For cooling-water trunking and saltwater services in the engine room and elsewhere, including fire mains, plumbing, and air-conditioning systems in ships, more resistant alloys are taking the place of copper or galvanized steel. The latter were formerly extensively employed, but they do not have adequate resistance to attack by seawater. Cu-10Ni-1.5Fe alloy has been widely utilized and normally gives excellent service. In some special naval applications, pipelines of 70-30 cupronickel are used and it has been found that adequate attention must be given to correct fabrication and installation techniques. Carbonaceous residues from fillers used in bending operations must be avoided or pitting corrosion may occur in service. Jointing materials of low corrosion resistance should not be used, silver brazing or appropriate welding methods being the correct techniques. Residual stresses, if present, can cause stress-corrosion failures of aluminum-brass pipelines in service.

Copper alloys in wrought or cast form are employed for other purposes in ships and marine installations, such as for propellers, bearings, valves, and pumps. For instance, aluminum-brass is used for heating coils in tankers carrying crude oil or petroleum products. However, some corrosion problems encountered in this and other applications on board ship have been described by Gilbert and Jenner.<sup>172</sup>

Cupronickels have been shown to possess extremely low long-term corrosion rates in quiet or slowly-moving seawater. The 90-10 alloy is of particular interest<sup>28,163</sup>; this alloy is now well established for use for pipelines on ships and it has become widely used for piping systems on floating production, storage and offloading vessels (FPSO's), and offshore platforms. In addition to its good corrosion resistance, 90-10 cupronickel has a high resistance to marine macrofouling providing that it is not cathodically protected. This has led to applications such as the construction or sheathing of ships' hulls, fish cages for aquaculture and cladding of steel offshore structures in the tidal/splash zones.<sup>9</sup>

Investigations into the effects of arsenic and phosphorus in single phase brasses on their susceptibility to intergranular attack and SCC in seawater have

shown that the normal additions of arsenic to inhibit dezincification ( $\sim 0.04\%$ ) have no significant adverse effect. Other possible consequences of exposing copper alloys to seawater which have been investigated included dealloying of aluminum bronzes<sup>109</sup> and the effects at bimetallic contacts.

Major efforts have been made to understand the nature of films formed on copper alloys in natural seawater. These films have quite different characteristics to those formed in sodium chloride solution, the differences being associated with the presence of organic material in the natural environment. However, the structure of the films is affected by variables such as water velocity, temperature, and oxygen content. Protective films often have a multilayered structure,<sup>157</sup> with an outer layer rich in iron providing impingement resistance and an inner layer giving chemical/electrochemical protection. With aluminum brass, a colloidal mixed hydroxide inner layer provides a buffering action, with tin-containing brass there is a tin-rich layer near the copper surface<sup>173</sup> and, with cupronickel, there is a chloride-rich layer which strongly inhibits the cathodic reaction. A study on Cu-Si alloys in seawater has found that the formation of copper silicide at the alloy surface acts to prevent corrosion.<sup>174</sup>

### 3.07.3.6 Effect of Exposure to Contaminated Environments

As with many metallic materials, failure of copper alloys may occur by cracking due to the combined influence of tensile stress and exposure to a debilitating environment due to the presence of a contaminant. Failures of brass components due to this form of stress corrosion cracking have been known for many years<sup>175</sup> and has been termed *season cracking*. In this case, the stresses in the material are produced in components during their manufacture and the contaminant is ammonia vapor produced by the natural decay of organic matter.

Only certain specific environments appear to produce stress corrosion of copper alloys, most notably ammonia,<sup>176-178</sup> ammonium compounds, or amines. Interestingly, pure copper does not suffer from ammonia-induced stress corrosion but will display the phenomenon in the presence of nitrites.<sup>179</sup> Stress corrosion can also occur with moist sulfur dioxide, sulfites, and some organic acids.<sup>180</sup> Mercury or solutions of mercury salts (which cause deposition of mercury), or other molten metals will also cause cracking, but the mechanism is undoubtedly

different.<sup>181</sup> Cracks produced by mercury are always intergranular, but ammonia, according to the exact conditions, may produce cracks which are fully transgranular, fully intergranular, or a mixture of both. As an illustration of this, Edmunds<sup>182</sup> found that mercury would not produce cracking in a stressed single crystal of brass, whereas ammonia could do so.

In certain circumstances, corrosion of copper alloys can occur through seemingly random interconnected microtunnels which spread out into the metal from what appears to be only a discoloration of the surface film. As a result of this phenomenon, through-thickness perforation of tube can result in weeks or months. This type of corrosion has been termed formicary corrosion due to its morphological similarity to an ants nest. Elliott<sup>183</sup> has produced a summary of knowledge of formicary corrosion up to 1999. The cause has been ascribed to contamination of the outside of the tube by carboxylic acids.

#### 3.07.3.6.1 Stress corrosion of brasses

Brasses containing only a few percent of zinc may crack under load if the stresses are high and the environment is sufficiently corrosive and most types of brass appear to be susceptible to the occurrence of this phenomenon of stress corrosion. An investigation of the effect of additions to 70–30 brass has been carried out by Wilson *et al.*,<sup>184</sup> who found that an addition of ~1% Si was markedly beneficial. Other additions were beneficial under some circumstances but none of the 36 additions tested accelerated stress-corrosion cracking. Further results have been given in later papers.<sup>185,186</sup>

In general, the susceptibility to stress corrosion in brasses appears to rise with an increase of zinc content, but in some circumstances alloys containing 64–65% Cu were found to be rather more affected than those containing 60% Cu.<sup>187</sup>

Many workers<sup>188–193</sup> have investigated the residual stresses introduced by different working processes in brasses of various compositions and the annealing treatments necessary to remove these stresses or reduce them to a safe level. A 'stress-relief anneal' at ~300 °C will usually lower internal stresses to comparatively small values without much effect on hardness of the material.

Specifications for brass products customarily include the provision for carrying out a mercurous nitrate test<sup>194,195</sup> (EN ISO 196:1995) to ensure that unduly high residual tensile stresses are not present, but a satisfactory result in this test does not

guarantee freedom from cracking in environments containing ammonia. More searching tests involving exposure to ammonia have therefore been devised, such as ISO 6957:1988. The standardization of stress-corrosion cracking tests and their correlation with service experience have been the subject of several papers.<sup>196–200</sup> A European standard for the assessment of susceptibility to SCC was published in 2006: EN 14977, Copper and copper alloys – detection of tensile stress – 5% ammonia test. Many authors<sup>201–205</sup> have described practical cases of stress-corrosion cracking usually involving tensile stresses applied in service. Two possible preventive measures are the use of coatings<sup>206–208</sup> or inhibitors.<sup>209</sup>

The behavior of a wide range of  $\alpha$ ,  $\alpha$ - $\beta$ , and  $\beta$  brasses in various corrosive environments was studied by Voce and Bailey and their results have been summarized by Whitaker.<sup>210</sup> Penetration by mercury and by molten solder was found to be intergranular in all three types of brass. In moist ammoniacal atmospheres, the penetration of unstressed brasses of all types was intergranular. Internal applied stresses accelerated the intergranular penetration of  $\alpha$  brasses and initiated some transgranular cracking. It also caused severe transgranular cracking of  $\beta$  alloys and transgranular cracking across the  $\beta$  regions in the two-phase brasses. Immersion in ammonia solution, however, caused intergranular cracking of stressed  $\beta$  brasses.  $\beta$  brasses containing 3% or more aluminum failed with an intergranular fracture when stressed at ~0.1% proof stress in air. The behavior of alloys of this type was subsequently studied by Perryman<sup>211</sup> and Bailey<sup>212</sup> who showed that cracking in air occurs only when moisture is present. It has been confirmed that  $\beta$  brasses are prone to crack in service.<sup>213</sup>

High-strength  $\alpha$ - $\beta$  brasses containing up to ~5% Al (with small amounts of Fe, Mn, Sn, etc.) used for propellers, parts of pumps, nuts and bolts, and similar applications usually give good service but occasionally suffer intergranular failure, for instance in contact with seawater. Examination of such failures usually reveals thin dezincified layers along the cracks, but it is often difficult to decide whether the crack or the dezincification occurred first.

The theoretical aspects of stress-corrosion cracking have attracted much attention in recent years. Among the copper alloys, the behavior of brasses in ammoniacal environments has been most studied. While cracking has been shown to be possible in contact with some other corrosive agents, ammonia has the most powerful effect. Evans<sup>214</sup> suggests that

this is because ammonia is a feeble corrodent which produces little attack except at regions such as grain boundaries or other lattice imperfections. Also, it prevents accumulation of copper ions in the crevices formed owing to the formation of stable complexes such as  $\text{Cu}[(\text{NH}_3)_4]^{2+}$ . The mode of cracking (intergranular or transgranular) can be affected by changes in composition of the brass or by changes in the nature of the environment.<sup>215</sup> Mattsson<sup>216</sup> found that, on immersion in ammoniacal solutions of different pH values, stressed brasses cracked most rapidly at pH 7.1–7.3 and that in this range black surface films formed on the metal. The role of tarnish films has been further studied subsequently.<sup>217–219</sup> Many authors have studied electrochemical<sup>220–235</sup> or metallurgical<sup>236–241</sup> aspects of the stress corrosion of copper alloys and discussed theories of the mechanism. Papers on the subject have been included in several symposia or conferences on stress corrosion of metals.<sup>242–244</sup> The stress cracking of brasses has been reviewed by Bailey<sup>245</sup> and other workers<sup>246–254</sup> and reviews of stress corrosion as a general subject have also been published.<sup>255–257</sup>

### 3.07.3.6.2 Stress corrosion of other copper alloys

Evidence indicates that pure copper is not likely to be susceptible to stress corrosion<sup>258–260</sup> but instances of the failure of copper are known, when it contains 0.4% As<sup>261</sup> or 0.02% P.<sup>258</sup> SCC has also been found to occur in copper–beryllium,<sup>262</sup> copper–manganese,<sup>263–265</sup> aluminum–bronzes,<sup>266,267</sup> tin–bronzes, silicon–bronzes, nickel silvers,<sup>268</sup> and cupronickels.<sup>268,269</sup> Most of these alloys are much less susceptible to cracking than brasses,<sup>270</sup> although under some conditions aluminum–bronzes can be particularly prone to cracking.<sup>271</sup> In ammoniacal environments, the cracking tends to be transgranular, and in steam atmospheres, intergranular cracking is favored.<sup>272</sup> Additions of 0.35% Sn or Ag are claimed to be effective in preventing intergranular cracking.<sup>273,274</sup> Aluminum–bronzes containing 2% Ni and 0.5–0.75% Si are claimed to have good resistance to stress corrosion,<sup>273,275</sup> although there is evidence that silicon bronzes can show accelerated intergranular fracture in the presence of moist air.

Thompson and Tracy<sup>258</sup> carried out tests in a moist ammoniacal atmosphere on stressed binary copper alloys containing zinc, phosphorus, arsenic, silicon, nickel, or aluminum. All these elements gave alloys susceptibility to stress corrosion. In the case of zinc, the failure time decreased steadily with increase

of zinc content, but with most other elements there was a minimum in the curve of concentration of alloying elements against time to failure. In tests carried out under a static load of  $70 \text{ MN m}^{-2}$ , these minima were found to occur at concentration levels of  $\sim 0.2\%$  P,  $0.2\%$  As,  $1\%$  Si,  $5\%$  Ni, and  $1\%$  Al. In most cases, the cracking was observed to be intergranular.

A series of slow strain rate tests have been carried out on high strength Cu–Ni–Al alloys in environments which could be encountered by the offshore oil and gas industry<sup>276</sup> and these have found that the application of a cathodic potential (as applied in cathodic protection) gives protection against stress corrosion. However, molybdenum disulfide greases mixed with seawater and greases containing bentone were found to promote stress corrosion as did the more well known debilitating species such as amines. Work on relating the microstructural aspects of these alloys to their possible susceptibility to stress corrosion has identified<sup>277</sup> that the production process should be undertaken in such a way that the presence of iron-rich phases on the grain boundaries is restricted, the material has a fine grain size and that it is supplied in an under-aged condition.

Cupronickels (90–10 and 70–30) have generally been considered immune to sulfide stress corrosion in most seawater environments.<sup>9</sup> However, there have been recent trials<sup>278</sup> in seawater containing severe sulfide levels of 100–1000 ppm which indicate a cracking possibility for the 90–10 alloy.

A related debilitating effect to stress corrosion cracking is hydrogen embrittlement, and it is interesting to note that copper alloys have not been reported to suffer from this phenomenon. In particular, testing has demonstrated that high strength Cu–Ni–Al and Cu–Ni–Sn alloys do not embrittle under hydrogen charging conditions<sup>277</sup> whereas nickel alloys containing copper and aluminum (Ni–Cu–Al) lose ductility under the same conditions. Detailed electrochemical work carried out by Pound<sup>279</sup> allowed him to suggest that this is because the internal hydrogen becomes associated with both reversible and irreversible trap sites. He postulates that the trap sites in a Cu–Ni–Al alloy are measurably more reversible than those in Ni–Cu–Al, preventing the former from being susceptible to hydrogen embrittlement.

### 3.07.3.7 Corrosion in Industrial Chemicals

A number of publications are available which give detailed information on the action of a wide range of chemicals on copper and copper alloys.<sup>280–285</sup>

When contemplating the use of copper-based materials for industrial purposes it is necessary to bear in mind that, even though a satisfactory life of the component may be obtained, possible difficulties may arise from the following other causes:

1. Copper compounds can be tolerated only in small amounts in potable waters or food substances. The WHO current safe concentration limit for copper in drinking water of  $2.0 \text{ mg l}^{-1}$ .
2. Copper compounds are highly colored, and a very small amount of corrosion may lead to staining and discoloration of products.
3. Stimulation of the corrosion of vital parts made of more anodic metals may occur if they are connected to copper.
4. Very small amounts of copper taken into solution may cause considerable corrosion of more anodic metals elsewhere in the system, particularly zinc,<sup>145</sup> aluminum,<sup>146</sup> and sometimes steel.<sup>286</sup> Small particles of copper deposited from solution set up local cells which can cause rapid pitting.

Despite these qualifications, copper and its alloys are used extensively and successfully in many types of chemical production equipment. Uses include condensers and evaporators, pipelines, pumps, fans, vacuum pans, and fractionating columns. Tin-bronzes, aluminum-bronzes, silicon-bronzes, and cupronickels are used in some circumstances because they present better corrosion resistance than copper or brasses.

#### 3.07.3.7.1 Acid solutions

Copper does not normally displace hydrogen, even from acid solutions, and it is therefore virtually unattacked in nonoxidizing conditions. For strongly reducing conditions in the temperature range 300–400 °C, corrosion resistance is comparable, if not better, than stainless steel. However, when copper alloys come into contact with most solutions, which invariably contain dissolved air, cathodic depolarization can occur which increases the chances that corrosion will take place.<sup>287</sup> Therefore, it is difficult to lay down any general recommendations for the use of copper in acid solutions, since the rate of attack significantly depends on the particular circumstances. Under fairly mild conditions copper or copper alloys are successfully used for handling solutions of hydrofluoric,<sup>280,288,289</sup> hydrochloric,<sup>280,290</sup> sulfuric,<sup>291</sup> phosphoric,<sup>280,292</sup> acetic, and other fatty acids.<sup>280,293</sup> Rates of corrosion, in general, increase with concentration of acid, temperature, amount of aeration,<sup>294,295</sup> and speed

of flow.<sup>296</sup> Tin-bronzes, aluminum-bronzes,<sup>297–299</sup> silicon-bronzes, and cupronickels are among the copper alloys most resistant to acids. For instance, aluminum bronze will withstand 50% sulfuric acid at 120 °C and 60% sulfuric acid at 30 °C. Silicon bronze is resistant to hydrochloric acid over the range 10% HCl at 70 °C/20% HCl at 50 °C/35% HCl at 15 °C. Brasses should not normally be used in acids. All copper-based materials are attacked rapidly by oxidizing acids such as nitric acid, strong sulfuric acid, or chromic acid (including dichromates) and also by hydrocyanic acid. The maximum temperature of operation of copper in dry HCl is 93 °C and in dry chlorine it is 200 °C.

The dissolution of copper and brasses in acid solutions has been studied by several authors.<sup>300–305</sup> In sulfuric acid, pitting attack has been found to occur in 95% sulfuric acid at 50 °C, in 80% sulfuric acid at 70 °C, and in 60% sulfuric acid at 100 °C. Various substances have been found to have an inhibiting effect on the rate of attack of copper or brasses in nitric acid<sup>306–310</sup> and in hydrochloric acid.<sup>311</sup>

#### 3.07.3.7.2 Neutral and alkaline solutions

Copper-based materials are resistant to alkaline solutions over a wide range of conditions,<sup>312</sup> but may be appreciably attacked by strong solutions, particularly if hot. Cupronickel alloys usually give the best results in alkaline solutions. Copper and its alloys should be avoided if ammonia, ammonium compounds, or organic amines are present<sup>313–317</sup> owing to the danger of both general corrosion and stress corrosion.

Copper is satisfactory for handling solutions of most neutral salts<sup>280,318</sup> unless aeration and turbulence are excessive. All exception is provided by those salts that form complexes with copper, such as cyanides, and solutions containing oxidizing agents, such as ferric or stannic compounds.

#### 3.07.3.7.3 Hydrogen sulfide pollution

Polluted and stagnant waters can be a source of corrosion to copper alloys because of the metal reaction with hydrogen sulfide to form sulfide surface films. Higher corrosion rates and pitting corrosion can result because the films do not provide the same protection as those normally formed. Sources of hydrogen sulfide include industrial waste, decomposition of organic matter, and sulfate reducing bacteria.

When there is little or no oxygen present in the system, then the corrosion rate of copper alloys with a sulfide film is only slightly higher than in aerated seawater.<sup>319</sup> However, when aerated seawater mixes with sulfide-containing seawater, higher rates of

corrosion can occur. Such corrosion is also velocity sensitive and is found to be more pronounced in regions of highest flow velocity.

A sulfide film can gradually be replaced by an oxide film in seawater during subsequent exposure to aerated conditions,<sup>9,162</sup> although this may take several days and high corrosion rates can be expected in the interim. However, if an established cuprous oxide film is already present, then periodic exposure to polluted water can be tolerated without damage to the film. Therefore, exposure to sulfides should be restricted wherever possible and this should be particularly so during commissioning and during the first few months of exposure to seawater, during which time the oxide film is maturing. Typical guidelines for commissioning or shut down/standby of copper alloy piping systems are given in **Table 8**.

The addition of ferrous ions to seawater systems, usually as a result of dosing with ferrous sulfate or by the use of a stimulated iron anode, has been found to improve the corrosion resistance of aluminum brass and cupronickels when exposure to polluted conditions are anticipated.<sup>76</sup> Other pretreatments have been investigated with variable success.<sup>76,166</sup>

The common cast alloys used for seawater systems are gunmetals, high tin bronzes, and nickel aluminum bronze. In clean water, nickel aluminum bronze is the favored alloy for pumps and valves<sup>319</sup> but 10% tin bronzes can be better in mildly polluted conditions, particularly for erosion resistance.

Francis has reported<sup>319</sup> that the presence of sulfides can reduce the temperature above which hot

spot corrosion can be found in heat exchangers from  $\sim 130^\circ\text{C}$  down to  $80^\circ\text{C}$ . This type of attack is caused by thermogalvanic effects under slow flow or stagnant conditions. Cupronickel (70–30) is the most susceptible alloy for hot spot corrosion and aluminum brass is the most resistant. Again, ferrous sulfate dosing, or higher flow rates, can provide improved resistance.

A microstructural study of the behavior of high strength Cu–Ni–Al alloy toward aqueous  $\text{H}_2\text{S}$  has been carried out using STEM and SEM surface analysis.<sup>320</sup> The morphology of the surface is shown in **Figure 7** together with a schematic diagram derived from microanalysis explaining the chemical composition of the various corrosion product layers formed. It was concluded that the large copper sulfide crystals were deposited on the surface following preferential corrosion of copper from the alloy surface. The general corrosion rate was about three times lower than that of 70–30 cupronickel as a result of the formation of an aluminum-rich oxide layer directly at the solid/solution interface.

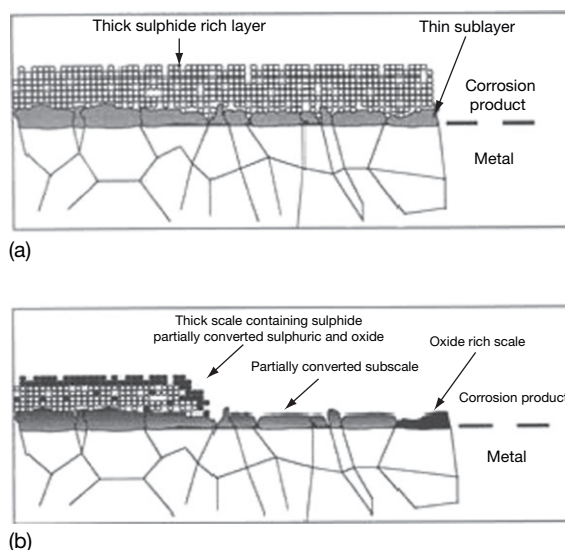

#### 3.07.3.7.4 Other chemicals

Copper and copper alloys are unsuitable in hydrogen peroxide<sup>279,321</sup> or molten sulfur.<sup>279,322</sup> Halogens have little action on copper at room temperature when dry, but are corrosive when wet. Hypochlorite solutions are corrosive.<sup>323</sup> Most organic compounds are without appreciable action,<sup>279</sup> although contact with moist acetylene should be avoided, as explosive compounds are formed. Moisture also accelerates

**Table 8** Guidelines for shutdown and standby conditions of a copper alloy piping system in order to avoid possible problems caused by the presence of sulfides

attack by halogenated organic compounds, particularly carbon tetrachloride and trichloroethylene, which hydrolyze to give traces of hydrochloric acid. Cupronickels show most resistance to these chemicals.

Copper alloys are widely used for handling hydrocarbon oils, although, if sulfur compounds are present, attack can be serious. The effects of synthetic detergents on copper have been investigated<sup>324,325</sup> and several authors<sup>279,326–328</sup> have discussed various aspects of the behavior of copper and its alloys in the food-processing industry, where direct contact with copper alloys can result in the alteration of taste or color.

### 3.07.3.8 High Temperature Oxidation and Scaling

Several authors have reviewed the literature on the oxidation and scaling of metals, including copper.<sup>329–332</sup>

#### 3.07.3.8.1 High temperature oxidation of copper

The volume ratio for cuprous oxide on copper is 1.7, so that an initially protective film is to be expected. Such a film must grow by a diffusion process and should obey a parabolic law. This has been found to apply for copper in many conditions, but other relationships have been noted. For instance, in the very early stages of oxidation, a linear growth law is found (e.g., at 1000 °C).<sup>333</sup>

At 180–290 °C, it has been determined<sup>334</sup> that the parabolic law first applies but, subsequently, this changes to a logarithmic relationship of the type shown in eqn [7]:

$$Y = K \log B(t + 1/B) \quad [7]$$

$B$  being a constant. However, other workers have reported a cubic relationship under some conditions. Evans<sup>335,336</sup> has shown how the effect of internal stresses in growing films may have various effects which can lead to any one of the three growth laws referred to above.

At medium and high temperatures<sup>337–345</sup> copper ultimately follows the parabolic law.<sup>346</sup> It has been shown using radioactive tracers<sup>347,348</sup> that the diffusion of copper ions in cuprous oxide is the rate-determining step at 800–1000 °C, and there is considerable evidence in favor of the view that metal ions move outwards through the film by means of vacant sites in the oxide lattice.<sup>133</sup>

When oxidation is a diffusion-controlled process, the oxidation rate should be related to the temperature by the Arrhenius relationship, eqn [8]:

$$K = A \exp(-Q/RT) \quad [8]$$

where  $K$  is the rate constant,  $A$  a constant,  $R$  the gas constant,  $T$  the absolute temperature, and  $Q$  the activation energy. Values which have been obtained for  $A$  and  $Q$  are summarized by Tylecote,<sup>349</sup> Pilling and Bedworth,<sup>350</sup> Feitknecht,<sup>351</sup> and others

and give values of  $Q$  of  $\sim 0.17$  MJ for temperatures of 700–1000 °C, while at lower temperatures (up to 500 °C) Vernon<sup>352</sup> and others have obtained values of about 85 kJ. These values are in agreement with calculations by Valensi,<sup>353</sup> based on the assumption that, at high temperatures, the oxidation proceeds by the reaction of oxygen with metallic copper to produce cuprous oxide while at lower temperatures the rate is determined by the reaction between oxygen and cuprous oxide to form cupric oxide.

At low temperatures (e.g., 300 °C) the film consists almost entirely of CuO. As the temperature increases, the film consists of a layer of Cu<sub>2</sub>O beneath a layer of CuO, the proportion of Cu<sub>2</sub>O increasing until, at high temperature, the film is almost entirely Cu<sub>2</sub>O. The precise composition of the film depends, however, on a number of factors, including temperature, time, and oxygen concentration in the atmosphere. Tylecote<sup>346</sup> has investigated the composition, properties, and adherence of scales formed on various types of copper at temperatures between 400 and 900 °C. At the higher temperatures, the scales formed on copper containing phosphorus were more brittle and less adherent than those formed on copper containing no phosphorus.

Studies have been carried out on the effects at high temperature of sulfur<sup>349</sup> and of atmospheres containing hydrogen sulfide,<sup>354–356</sup> steam,<sup>357,358</sup> sulfur dioxide,<sup>358</sup> and hydrogen chloride.<sup>358</sup>

### 3.07.3.8.2 High temperature oxidation of copper alloys

In the case of copper alloys which contain elements which are more noble than copper, the resulting surface oxide will be substantially pure copper oxide as the oxides of the noble metals have higher dissociation pressures than the copper oxides. Conversely, for alloys containing baser metals, the alloying element will appear as an oxide in the scale often in greater concentration than in the alloy itself, and sometimes to the exclusion of copper oxides. The dissociation pressures of many oxides have been calculated by Lustman.<sup>359</sup>

Whether the rate of oxidation of an alloy of copper with a base metal is less or more than that of copper will depend on the concentration of the alloying element and the relative diffusion velocities of metal atoms or ions in the oxide layers. There is extensive literature on the oxidation behavior of copper alloys.<sup>346,347,360–367</sup> According to Wagner's theory<sup>368–371</sup> the rate of oxidation will be largely influenced by the electrical conductivity of the film

and this theory is supported by the fact that the alloying elements giving maximum oxidation resistance to copper, that is, beryllium, aluminum, and magnesium, form oxides having very low conductivities, as shown by Price and Thomas.<sup>372</sup> Wagner calculated that when sufficient aluminum was present in copper to cause the formation of an alumina film, the oxidation rate should be decreased by a factor of more than 80 000. Experiment showed the factor to be only 36, but when Price and Thomas carried out initial oxidation under only slightly oxidizing conditions, producing only a film of alumina, the oxidation rate on subsequent exposure to full oxidizing conditions was decreased by a factor of  $\sim 240$  000. Hallowes and Voce<sup>358</sup> found that selective oxidation of a 95Cu–5Al alloy by this method gave protection from atmospheric oxidation up to 800 °C unless the film was scratched or otherwise damaged, or the atmosphere contained sulfur dioxide or hydrogen chloride.

The effects on oxidation resistance of copper as a result of adding varying amounts of one or more of aluminum, beryllium, chromium, manganese, silicon, and zirconium are described in a number of papers.<sup>360–367</sup> Other authors have investigated the oxidation of copper–zinc<sup>373,374</sup> and cupronickel alloys,<sup>374,375</sup> the oxidation of copper and copper–gold alloys in carbon dioxide at 1000 °C<sup>376</sup> and the internal oxidation of various alloys.<sup>377–379</sup>

Copper alloys have been used extensively in high-pressure feed-water heaters in power generating plant.<sup>380</sup> Experience has shown that when such heaters are operated intermittently, 70Cu–30Ni or 80Cu–20Ni alloy tubes suffer fairly rapid and severe steam-side (external) oxidation with the formation of exfoliating scales. This corrosion, which may be associated with ingress of air during shutdowns, has been the subject of several published papers.<sup>381–385</sup> The behavior of other alloys for feed-water heater service has also been discussed.<sup>380,386–388</sup>

## 3.07.4 Protective Measures

The good corrosion behavior of copper and copper alloys is dependent upon correct choice of material, good design of equipment, and proper methods of operation. Brasses and bronzes may often be effectively protected by polishing followed by periodic waxing. If proper attention is given to these factors, there will usually be no need for protective measures. In special cases, however, for example, to prevent the dissolution of small amounts of copper or to maintain

a high-grade finish, metallic coatings of one or more of the following metals may be applied: tin, lead, nickel, silver, chromium, rhodium, or gold. In other cases painting, varnishing, or lacquering may be desirable, or if the conditions are very severe (as in some corrosive soils) heavier protection such as bituminous or plastic coatings may be necessary. Brasses that are liable to suffer dezincification or stress corrosion may need protection where other copper alloys would be satisfactory in an unprotected condition. Sometimes use is made of the principles of cathodic protection, for example, steel 'protector blocks' in condenser water-boxes.

In some circumstances, use of inhibitors may be a desirable remedial measure. For instance, benzotriazole (BTAH) has been found of considerable value for preventing staining and tarnishing of copper products.<sup>389</sup> The characteristics of the behavior seen indicate that an inhibiting film is formed by adsorption of neutral BTAH molecules on the copper surface followed by adsorption of a thin layer of copper BTAH in polymeric form. Also, a synergistic effect has been found when BTAH and iodide ions are used together to prevent copper corrosion in sulfuric acid.<sup>390</sup> Sodium diethyldithiocarbamate also has useful inhibiting properties.<sup>391</sup> Other types of inhibitors can be of value in condensate systems<sup>392,393</sup> and in acid solutions.<sup>305–310</sup> Reviews have been given of corrosion inhibitors for copper<sup>394</sup> and brasses.<sup>395,396</sup> The effects and efficiencies of various inhibitors continues to be the subject of much research.<sup>397–400</sup> Low concentrations (0.1 mM) of amino acids (glycine and cysteine) have been demonstrated to provide over 95% inhibition efficiency for 95–5 cupronickel corrosion.<sup>401</sup>

The danger of accelerated attack on copper-base materials due to coupling with other metals is small in many environments since copper is usually the cathodic member of the couple, but precautions are often necessary to prevent excessive corrosion of the anodic member. Surveys of the behavior of couples involving copper and copper alloys have been given.<sup>319</sup> Titanium, high nickel alloys, and super stainless steels can be sufficiently more noble than copper alloys in seawater environments to cause galvanic attack of the copper alloy and electrical isolation or insulated spool pieces may be required. This is less of a problem in chlorinated systems as prevention of the biofilm can reduce the efficiency of the cathode.<sup>319,402</sup> Another material that has been found capable of accelerating attack on copper in practice is graphite; hence graphitic paints or graphite in

gasketing, etc., are undesirable. Occasionally the action between different copper-based materials may be appreciable particularly if the relative surface areas are unfavorable, for example, gunmetal may stimulate the corrosion of copper or brass in seawater and due care should be taken.

### 3.07.5 Areas of Future Development

#### 3.07.5.1 Antimicrobial Benefits of Copper Corrosion

The formation of cuprous  $\text{Cu}^+$  and cupric ions  $\text{Cu}^{2+}$  has been described earlier. The ability of copper to gain and lose outer electrons is the source of many of copper's important physical properties such as high electrical and thermal conductivity, chemical stability, and its reddish color. Copper ions also play a crucial role in copper's antimicrobial action and the main hypotheses for the mode of actions in damaging the functionality of a cell of a microorganism are:

1. Their competing with and hindering uptake of major minerals such as sodium and potassium. This causes serious imbalances in the mineral composition of the cell of the microorganism.<sup>403</sup>
2. Their binding to proteins inside the cell which do not require copper, creating a dysfunction of that protein.<sup>404,405</sup>
3. Their causing oxidative damage, thereby damaging the cell wall and other cellular structures and finally causing bacterial cell death.<sup>406</sup>

Recent work<sup>407–409</sup> has shown the effectiveness of copper in inactivating pathogens such as *Escherichia coli*, Meticillin-resistant *Staphylococcus aureus* (MRSA), and *Influenza A* and in reducing environmental contamination in a clinical setting.<sup>410,411</sup>

#### 3.07.5.2 Alloy Developments

Cupronickel alloys in particular are being developed for applications in seawater and oil and gas well environments. Copper nickel chrome (DEF STAN 02-824) cast components are beginning to replace those made from nickel aluminum bronze when long-term seawater corrosion resistance is required. This is due to the fact that, after 10 years of seawater service, only such components have been found to have lost only  $\sim 0.15$  mm from their original thickness through corrosion, performing significantly better than cast nickel aluminum bronze under the same conditions.<sup>412</sup> Cu–Ni–Al and Cu–Ni–Sn alloys are

being developed as high strength corrosion resistant alloys for seawater applications requiring hydrogen-embrittlement-free, antigalling properties, and as alternative corrosion resistant, nonmagnetic bearing alloy to Be–Cu in directional oilfield drilling equipment.

Shape memory effect alloys have recently been under development for use in electronics and dentistry. Those based on Cu–Al and Cu–Ag–Al have been found to exhibit curious electrochemical effects during dissolution in alkali media if oxygen is present.<sup>413</sup> This has been explained in terms of fast preferential dissolution of aluminum followed by the slow transport of aluminate ions from the surface. This influences the formation of Cu<sub>2</sub>O, which is the main corrosion reaction, such that an unusual oscillatory electro-potential effect is produced.

## Acknowledgements

This section is comprised of a revised version of the chapter by P.T. Gilbert, which appeared in the previous edition. This, in turn, was based on ‘Chemical Properties and Corrosion Resistance of Copper and Copper Alloys,’ which formed Chapter XVIII of the American Chemical Society Monograph No. 122, ‘*The Science and Technology of the Metal its Alloys and Compounds*,’ edited by Professor Allison Butts, and published by the Reinhold Publishing Corporation, New York, in 1954. Acknowledgement is hereby made to the Reinhold Publishing Corporation for permission to make derivations from this work. The revisions of the current chapter have also been contributed to by Peter Webster, Technical Consultant, and Angela Vessey, Director, Copper Development Association UK, Claes Taxén of KIMAB, Sweden and Rolf Sundberg of Västerås, Sweden, to whom further acknowledgements are given.

### 3.08.1 Introduction

Having been discovered some 180 years ago, aluminum has a relatively short history and only recently completed its first century of commercial manufacture. The key to its extensive use today is its corrosion resistance and its extreme versatility that make it suitable for a wide range of products from household foil to armor plate and the essential construction material for generations of aircraft and space vehicles. Aerospace applications, which demand strength, toughness, corrosion resistance and light weight, have provided the greatest stimulus for alloy development and corrosion research, which continues even today.<sup>1</sup> Durable aluminum has provided a vast web of power transmission cables, cladding for all types of buildings and the versatile extruded section for glass house construction. It is increasingly the metal chosen for reducing the weight, thereby reducing emissions from the world's vast and rapidly expanding population of cars and trucks.

Aluminum and its alloys offer a diverse range of desirable properties that can be matched precisely to the demands of each application by the appropriate choice of composition, temper and fabrication mode. Aluminum can be rolled, forged, slit and sheared and shaped by extrusion through dies of a multiplicity of shape or can be cast directly into shaped products. In addition to its low density and high corrosion resistance, its other major attributes are its high thermal and electrical conductivity, heat and light reflectivity, cryogenic compatibility, nonferromagnetic property as well as its hygienic and nontoxic qualities for food contact applications.<sup>2</sup>

Aluminum as an engineering material ranks in tonnage use only behind iron and steel, and its growth in production has been continually increasing year by

year. The global tonnage shipped in 2007 was 60 Mt, of which 37 Mt was provided by primary production and 23 Mt by recycled scrap.<sup>3</sup> Aluminum is unique in its high level of recyclability, which can compensate for the high energy cost of its primary production.

Aluminum is an essential material for modern economies and often substitutes as the preferred material for steel and plastics in automotive and building applications; copper in electricity production and transmission; magnesium, titanium, composites and plastics in aerospace and defense applications; steel, plastics and glass in packaging applications; and wood and vinyl for building and construction applications.

This chapter provides a general, yet concise, account of the corrosion behavior of aluminum and its alloys with reference to their classification, processing and surface treatment.

### 3.08.2 Historical Perspective

Aluminum was first produced in impure form in 1825 by Hans Christian Ørsted and in pure form in 1827 by Friedrich Wöhler. The first commercial preparation of aluminum was in 1855 in France when Henry Etienne Sainte-Claire Deville reduced aluminum chloride with sodium. He also, most likely, conceived the idea of the electrolysis of aluminum oxide dissolved in cryolite, which in 1886 was used independently by Charles Martin Hall in the United States and Paul Héroult in France for the development of electrolytic extraction of high-purity aluminum in an economical manner and remains the basis for production even today.<sup>4,5</sup> Before the Hall-Héroult process was developed, aluminum was more valuable than gold and was used for dinner plates by Napoleon

III and the apex of the Washington Monument in 1884. Commercial production started in 1888 at the Pittsburgh Reduction Company, today known as Alcoa, and in 1889 in Switzerland at Aluminium Industrie, now part of Alcan.

Aluminum is the most abundant metal and comprises about 8% of the earth's crust. It occurs naturally as bauxite, the name given to its ore containing 30–50% hydrated alumina (along with impurities including iron oxide, titania and silica). The processing of bauxite is carried out by the chemical process invented by Karl Joseph Bayer in 1888,<sup>6</sup> which converts bauxite to alumina by digestion in caustic soda followed by precipitation and calcination. Impurities from bauxite and from the steel vessels and pipe-work of the alumina plants have a significant influence on the corrosion behavior of aluminum and its alloys.

The Hall–Héroult process is carried out in aluminum primary production plants, known as smelters, where the alumina from the Bayer plant is dissolved in molten cryolite, and electrolysis is carried out in an electrolytic reduction cell (or ‘pot’) consisting of baked carbon anode rods (which are consumed), a carbon-lined vessel to hold the electrolyte and a molten pool of liquid aluminum (the cathode).<sup>4,5</sup> The reduction cell is operated at about 950 °C. The anodes are consumed during the process as they react with the oxygen coming from the alumina. A typical smelter has hundreds of cells arranged in potlines operating at currents up to 500 kA. All potlines built since the early 1970s use prebake anode technology, where the anodes, manufactured from a mixture of petroleum coke with coal tar pitch binder, are prebaked in separate anode plants. In the earlier Soederberg technology, the carbonaceous mixture is fed directly into the top part of the pot, where self-baking anodes are produced using the heat released by the electrolytic process. Potlines of this type are being progressively phased out.

At regular intervals, molten aluminum is tapped from the pots and is transported to the cast house where it is alloyed in holding furnaces by the addition of other metals, cleaned of oxides and gases and then cast into ingots. These can take the form of extrusion billets for extruded products, or rolling ingots for plate, sheet and strip products, depending on the way they are to be further processed. Aluminum castings are produced by foundries using a number of molding techniques to manufacture shaped components.

Generally, the purity of aluminum from electrolysis cells is adequate (i.e., 99.7–99.9%) for alloying,

the main impurities being iron and silicon together with lower levels of zinc, magnesium, manganese and titanium; however, if high- or super-purity aluminum is required, a second stage of refining is carried out in a three-layer Hoopes cell producing purities between 99.99% and 99.999%. Higher purities can be achieved by zone-refining super-purity aluminum. World aluminum production grew rapidly from 180 kt in 1918 to 2 Mt in 1952 to 20 Mt in 1989. Since that time, the rate of increase has been more modest, rising steadily to 24 Mt in 2000 and recently, more rapidly to 37 Mt in 2007. Aluminum has been traded on the London Metal Exchange (LME) since 1978, and from 1985, the LME price was adopted as the market price. Over the past 30 years, the average LME quoted price of aluminum has been \$1.5 per kilogram but has ranged between \$1.00 and \$3.00 per kilogram depending on the variation in supply and demand.<sup>7,8</sup>

From a corrosion perspective, aluminum has been a remarkably successful metal, and many of the earliest artifacts remain like the mill-finished roof of the church of St. James in Rome built in 1897 and the statue of Eros by Albert Gilbert unveiled in London in 1893. The aluminum industry maintained strong corrosion technology support groups for many years as aluminum production and its range of applications expanded. The major corrosion issues addressed during this time were the tropicalization of aluminum alloys containing magnesium, the stress corrosion cracking of alloys used in aerospace applications, the galvanic corrosion of aluminum in architectural and automotive applications and, most recently, the filiform corrosion of painted aluminum sheet in both architectural and automotive applications. The most significant aluminum corrosion challenges at present are the ramifications from the elimination of chromates and the tolerance of increased impurity levels due to the increased use of recycled metal.

### **3.08.3 Production and Types of Aluminum Alloys**

#### **3.08.3.1 Aluminum Production**

Bauxite production has increased from 144 Mt worldwide in 2002 to 178 Mt in 2006. Most of this is mined from open cast mines in Australia (62 Mt), Brazil and China (both 20 Mt) followed by Guinea (15 Mt), Jamaica (15 Mt), and India (13 Mt). In 2006, Alcoa, Chinalco, Alcan, Rusal and BHP Billiton accounted for or controlled almost 60% of the

69 Mt of worldwide alumina production from the 178 Mt of bauxite.<sup>9</sup> The largest alumina producers in 2006 were Australia (18 Mt) and China (14 Mt). Like many commodities, alumina is sold both on spot prices and contract terms, for which it is typically priced between 11.5% and 13.5% of the aluminum price quoted on the LME. The recent rapid growth in Chinese demand for aluminum has led to a predicted increase in annual demand from 69 Mt per year in 2006 to 88 Mt per year by 2011. The largest producers of primary aluminum in 2003 were China (5.5 Mt), Russia (3.5 Mt), Canada (2.8 Mt), United States (2.7 Mt), Australia (1.8 Mt) and Norway (1.1 Mt). By 2007, Chinese production had increased to 12.6 Mt out of the total world primary production of 34 Mt.<sup>9</sup> The amount of electrical energy to produce aluminum has been reduced from more than 50 kWh kg<sup>-1</sup> in 1890 to 16.1 kWh kg<sup>-1</sup> in 1990 and to 15.2 kWh kg<sup>-1</sup> in 2006.

Four tons of bauxite is used to produce 2 tons of alumina, which then produces 1 ton of aluminum. The industry average emissions associated with primary aluminum production is 9.73 kg CO<sub>2</sub>e per kilogram, 55% of this from electricity generation, so this varies considerably depending on how the electricity is generated.<sup>3</sup> Historically, over 50% of the electricity used to produce aluminum has been hydroelectrically generated, and although it is expected that this trend will continue, recently significant smelter capacity has been installed, particularly in the Middle East, using gas. Aluminum production consumes 3% of the world's electricity and about 10% of its hydropower.

The aluminum industry maintains a close watch on the composition of primary aluminum by regular chemical analysis of samples from each individual electrolysis cell. Purity is calculated by subtracting all the trace element concentrations from 100%. Trends are noted with respect to age of the cell, anode technology and alumina source, as well as the use of recycled alumina from the environmental control systems (scrubbers) used in smelters that are used to trap elements that volatilize from reduction cells. Use of this scrubber alumina results in higher levels of nickel, lead, gallium and vanadium. From the corrosion perspective, the most significant impurities are iron (typically 0.03–0.2 wt %) and silicon (0.03–0.1 wt%) and the lower levels of elements such as copper, manganese, nickel, titanium, zinc, vanadium and gallium. Volatile elements such as sodium, calcium and phosphorous are removed by flux treatments prior to ingot casting.

Aluminum and its alloys are readily recyclable, with recycled scrap providing an increasingly important and growing contribution of 23 Mt per year to the more than 60 Mt total annual metal supply.<sup>3,10</sup> The ever-growing environmental concerns over raw material processing and primary aluminum production as well as the favorable economics of recycling have led to a strong secondary aluminum production industry based on reclaimed scrap accounting for about 30–35% of total aluminum production since the early 1990s. The recycling of aluminum requires 95% less energy than that is required for primary aluminum production, and recycling of used aluminum products generates only 0.5 kg of CO<sub>2</sub>e per kilogram of aluminum produced.

However, in order to meet the mechanical and corrosion performance requirements of many alloy and product specifications, much of the recycled metal must be 'sweetened' with primary metal to reduce impurity levels. The result is that in many cases (except beverage cans) recycled metal tends to be used primarily for lower grade casting alloys and products. While a certain amount of this is acceptable, the recycle-friendly world will be truly optimized only when the recycle loop is closer to a closed loop within a number of product lines. Elements that increase in the recycled metal are mainly iron and silicon, and other elements such as magnesium, nickel and vanadium.<sup>11</sup> It is generally advisable to separate wrought alloys from cast alloys.

The total weight of aluminum products in use in 2006 was estimated to be 584 Mt, of which 32% is in building products, 28% in transport applications, 28% in engineering and cable, 1% in packaging and 11% in other products. Since the 1880s, close to 800 Mt of aluminum have been produced, and about three-quarters of this metal, more than 580 Mt, is still in productive use. This is a testament to the excellent corrosion resistance and recyclability of aluminum in almost all its applications. Recycling the metal currently in use would equal 17 years' primary aluminum output.<sup>3</sup>

### 3.08.3.2 Physical Metallurgy

The properties of aluminum alloys (mechanical, physical and chemical) depend on both alloy composition and alloy microstructure as determined by casting conditions and the thermomechanical processing history. While certain metals alloy with aluminum rather readily,<sup>12</sup> comparatively few have sufficient solubility to serve as major alloying elements. Of the commonly

used alloying elements, magnesium, zinc, copper and silicon have significant solubility, while a number of additional elements (with <1% total solubility) are also used because of the important improvements to alloy properties they confer. Such elements include manganese, chromium, zirconium and titanium.<sup>1,13</sup>

The low yield strength of pure aluminum (~10 MPa) mandates strength increase by alloying for subsequent engineering applications. The simplest strengthening technique is 'solution hardening,' whereby alloying additions as solute must have appreciable solid solubility over a wide range of temperatures and must remain in solution after any heating/cooling cycles, ultimately not being removed from solution by reacting with elements to form insoluble phases. Solid solution strengthening can lead to strength increases of about a factor of 2–4.

However, the most significant increase in strength for aluminum alloys is derived from age-hardening, and in the extreme, this can result in strengths up to 800 MPa. Age-hardening requires a decrease in solid solubility of one (or more) alloying elements with decreasing temperature. The age-hardening process can be summarized by the following stages

- solution treatment at a temperature within a single-phase region to dissolve the alloying element(s);
- quenching or rapid cooling of the alloy to obtain what is termed a supersaturated solid solution;
- decomposition of the supersaturated solid solution at ambient or moderately elevated temperature to form finely dispersed (nanoscale) precipitates.

The fundamental aspects of decomposition of a supersaturated solid solution are complex and still under debate.<sup>14–16</sup> Typically, however, Guinier–Preston (GP) zones and intermediate phase (as shown in **Figure 1**) are formed as precursors to the equilibrium precipitate phase.<sup>13</sup>

In addition, increases in yield strength may also be achieved by grain refinement by exploiting the Hall–Petch relationship.<sup>1</sup> Grain refinement in aluminum alloys is achieved at the casting stage (by additions of small amounts of low-solubility additions such as Ti and B to provide grain nuclei) or by recrystallization control using dispersoids (formed by making trace alloying additions of Cr, Zr or Mn to promote submicron-sized insoluble particles which subsequently restrict or pin grain growth).

Strength development can be further enhanced or modified by careful thermomechanical processing which may include heat treatments such as duplex

**Figure 1** Dark field scanning transmission electron micrograph of fine precipitate  $\text{Al}_2\text{CuMg}$  particles in an Al–Mg–Cu–Si alloy – imaged down the <100> zone axis. Courtesy of Nick Birbilis.

aging and retrogression and reaging. Maximum hardening in commercial alloys is often achieved when the alloy is cold-worked by stretching after quenching and before aging, increasing dislocation density and providing more heterogeneous nucleation sites for precipitation.<sup>14</sup>

In reality, the microstructures developed in aluminum alloys are complex and incorporate a combination of equilibrium and nonequilibrium phases. Typically, commercial alloys have a chemical composition incorporating up to 10 deliberately made alloying additions. It is prudent, from a corrosion point of view, to understand the role that impurity elements have on the microstructure. While not of paramount significance to alloy designers, impurity elements such as Fe and Si with additional elements form insoluble/high-melting-point compounds that form constituent particles at the alloy casting stage. These constituent particles are comparatively large and irregularly shaped, with characteristic dimensions ranging from 1 to 10  $\mu\text{m}$ . These particles are formed during alloy solidification and are not appreciably dissolved during subsequent thermomechanical processing. Rolling and extrusion tend to break up and align constituent particles into bands within the alloy as shown in **Figure 2**. Often, constituents are found in colonies made up of several different intermetallic compound types. Because these particles are rich in alloying elements, their electrochemical behavior is often significantly different from that

**Figure 2** Scanning electron micrograph of constituent particles in AA7075-T651 imaged in the backscattered electron mode. Courtesy of Katja Meyer.

of the surrounding matrix phase. In most alloys, pitting is associated with specific constituent particles present in the alloy.<sup>17,18</sup> A range of alloying elements are found in constituent particles: examples include  $\text{Al}_3\text{Fe}$ ,  $\text{Al}_6\text{Mn}$  and  $\text{Al}_7\text{Cu}_2\text{Fe}$ .

### 3.08.3.3 Description of Alloys and Tempers

Traditionally, the global prescription of aluminum alloys for use in engineering was difficult owing to the alloy designations differing from country to country.<sup>1</sup> For this reason, the introduction of an International Alloy Designation System (IADS) introduced in the 1970s was a welcome rationalization and advance. The IADS, and its European Standard equivalent (EN 573), give each wrought alloy a four-digit number of which the first digit is assigned on the basis of the major alloying element(s), as is summarized in [Table 1](#), along with the associated temper description.

In the case of cast aluminum alloys, the alloy designations used in a global sense principally adopt the notation of the Aluminium Association system summarized in [Table 2](#). The casting compositions are described by a four-digit system which incorporates three digits followed by a decimal. The .0 decimal indicates the chemistry limits applied to an alloy casting; the .1 decimal indicates the chemistry limits for ingot used to make the alloy casting; and the .2 decimal indicates ingot composition but with somewhat different chemical limits (typically tighter, but still within the limits for ingot).<sup>19</sup> Generally, the XXX.1 ingot version can be supplied as a secondary product (remelted from scrap, etc.), whereas the XXX.2 ingot version is made from primary aluminum. Some alloy designations include a letter. Such

letters, which precede an alloy number, distinguish between alloys that differ only slightly in percentages of impurities or minor alloying elements (e.g., 356.0, A356.0, B356.0 and F356.0).

The temper designation system adopted by the Aluminium Association is similar for both wrought and cast aluminum alloys. Comprehensive details of alloy properties and characteristics are provided in the publications of the major aluminum companies and independent organizations.<sup>19</sup> Aluminum alloys tend to fall into several distinct groups, sometimes with apparently small differences within the group. Characteristics that could influence the selection of the most appropriate wrought products for a specific application are tabulated (in [Table 4](#)), but further details are provided as successful utilization of aluminum begin with the selection of alloy.

#### 3.08.3.3.1 Pure aluminum

Corrosion resistance of unalloyed aluminum increases with increasing metal purity. The use of the 99.8% and 99.9% grades is usually confined to those applications in which very high corrosion resistance or ductility is required. The chemical industry can advantageously use these purities for handling some products, but because of their low mechanical strength, they are sometimes used as a cladding material for a stronger substrate. Decreasing the purity results in modestly increased strength for the 99% and 99.5% grades, which still retain a high resistance to corrosion. The 99% pure metal may be considered the more useful general-purpose metal for lightly stressed applications such as cooking utensils. These alloys are known as the 1xxx series alloys, and the last two of the four digits indicate the minimum aluminum percentage. For example, 1050 is aluminum with a minimum purity of 99.5%. Alloys for electrical use are of special composition (i.e., AA1350 conductor alloys).

#### 3.08.3.3.2 Manganese-containing alloys

Manganese has a relatively low solubility in aluminum but improves its corrosion resistance in solid solution and can moderate the harmful influence of iron-bearing primary intermetallic phases. Additions of manganese of up to 1% form the basis for an important series of non-heat-treatable (3xxx series) wrought alloys, which have good corrosion resistance, moderate strength and high formability. For example, AA3003 displays a tensile strength of  $\sim 110$  MPa. In sheet form, its attractive combination of properties has resulted in large tonnages being used in buildings cooking utensils, and many general engineering

applications. The predominant architectural sheet alloys are AA3005 and AA3105, and alloys such as AA3104 are used for beverage cans because of their deep-drawing capability.

### 3.08.3.3.3 Magnesium-containing alloys

Magnesium that has a relatively high solubility in aluminum can impart substantial solid solution strengthening and improvement of work-hardening characteristics. The 5xxx series alloys (containing  $<7\%$  Mg) do not age-harden. Nominally, the corrosion resistance of these weldable alloys is good, and their mechanical properties make them ideally suited for structural use in aggressive conditions. These alloys are used both for boat and shipbuilding, for which a long history of satisfactory corrosion

performance is on record, and for automotive structural applications. However, elevated temperatures should be avoided, since for alloys containing more than 3 wt% Mg, the precipitation of  $\beta$ -type phase ( $\text{Mg}_2\text{Al}_3$ ,  $\text{Mg}_5\text{Al}_8$ ) over a period of time can lead to serious corrosion in the form of intergranular attack or stress corrosion cracking. Fully work-hardened AA5456 (Al–4.7Mg–0.7Mn–0.12Cr) has a tensile strength of 385 MPa.

#### **3.08.3.3.4 Silicon- and magnesium–silicon-containing alloys**

Silicon additions alone can lower the melting point of aluminum while simultaneously increasing fluidity, which is very important and is largely the basis of aluminum casting alloys and the associated shape-casting industry. These alloys are making an increasingly important contribution in automotive applications for engine and drive train components. Generally, corrosion issues with aluminum casting alloys are rare or at least under-reported unless they are in contact with other metals, fasteners or fixtures that promote galvanic corrosion. Wrought 4xxx series aluminum–silicon alloys are used extensively as cladding materials for brazing alloys. Where free machining characteristics are required, this may be achieved by additions of cadmium, antimony, tin or lead.

The heat-treatable Al–Mg–Si alloys are predominantly structural materials, all of which have a high resistance to corrosion, immunity to stress corrosion cracking (SCC) and a satisfactory degree of weldability. These 6xxx series alloys are mainly used in extruded form, although increasing tonnages of automotive closure sheet are being produced. Magnesium and silicon additions are made in balanced amounts to form quasibinary Al– $\text{Mg}_2\text{Si}$  alloys, or excess silicon additions are made beyond the level required to form  $\text{Mg}_2\text{Si}$ . Alloys containing magnesium and silicon in excess of 1.4% develop higher strength upon aging. AA6061 (Al–1Mg–0.6Si–0.25Cu–0.2Cr) in the United States and AA6063 (Al–0.6Mg–0.4Si–0.10Cu) in the EU are used as general-purpose building materials. Automotive closure sheet is made from AA6016 in the EU and AA6111 in North America.

#### **3.08.3.3.5 Copper- and copper–magnesium-containing alloys**

Copper is one of the most common alloying additions to aluminum since it has both good solubility and a significant strengthening effect by its promotion of age-hardening response. Copper is added as a major

alloying element in the 2xxx series of alloys. The copper–magnesium alloys led to the accidental discovery of age-hardening by Wilm in 1906.<sup>20</sup> These alloys were the foundation of the modern aerospace construction industry, and, for example, AA2024 (Al–4.4Cu–1.5Mg–0.8Mn) can achieve strengths of up to 520 MPa depending on temper. Such Al–Cu–Mg alloys develop their strength by precipitation of the S-phase ( $\text{Al}_2\text{CuMg}$ ).

#### **3.08.3.3.6 Zinc- and zinc–magnesium-containing alloys**

Zinc is added to certain types of casting alloys, and wrought binary aluminum–zinc alloys are used as clad layers to sacrificially protect aerospace and armor alloys. However, binary alloys show a limited age-hardening response, which is significantly increased by the addition of magnesium and copper. The Al–Zn–Mg alloy system provides a range of commercial compositions, primarily where strength is a major consideration along with weldability, although this requirement limits the maximum amount of copper that can be added to less than 0.3 wt%. Al–Zn–Mg–Cu alloys have traditionally offered the greatest potential for age-hardening, and as early as in 1917, a tensile strength of 580 MPa was achieved; however, such alloys were not suitable for commercial use until their high susceptibility to stress-corrosion cracking could be moderated. Military and commercial aerospace needs following World War II led to the introduction of a range of high-strength aerospace alloys of which AA7075 (Al–5.6Zn–2.5Mg–1.6Cu–0.4Si–0.5Fe–0.3Mn–0.2Cr–0.2Ti) is perhaps the most well known.

The high-strength 7xxx series alloys derive much of their strength from the precipitation of the  $\eta$ -phase ( $\text{MgZn}_2$ ) and its precursor forms. The heat treatment of the 7xxx series alloys is complex, involving a range of heat treatments that have been developed to balance strength and stress corrosion cracking performance.<sup>21</sup>

#### **3.08.3.3.7 Lithium-containing alloys**

Lithium is soluble in aluminum to a maximum level of about 4 wt%; however, as this is 16 at.%, it means that significant density improvements result from lithium additions. The strong response of these alloys to heat treatment has led to intense research and development on these alloys of high specific strength and stiffness for aerospace applications. Although research into Al–Li alloys dates back to the 1950s, there are continuing

concerns relating to low ductility and poor toughness and low corrosion resistance.

Recent studies have focused on Al–Cu–Li, Al–Li–Mg and Al–Li–Cu–Mg alloys (including the use of minor Ag additions). These alloys derive their strength from age-hardening, involving intermetallics such as  $\text{Al}_2\text{CuLi}$  and  $S'$  phase resulting in strengths in excess of 700 MPa.<sup>22</sup> Such alloys are very attractive for aerospace applications such as, for example, the launching of payloads into space orbit. The new Airbus A350XWB aircraft (expected 2013) is proposed to be predominantly comprised of Al–Li-based alloys. The corrosion challenge that remains to be resolved is the susceptibility to intergranular corrosion (IGC).

### 3.08.3.3.8 Other alloys classified as 8xxx alloys

Certain alloys high in lithium are classified as 8xxx alloys. This designation also includes alloys containing high levels of iron and manganese near the ternary eutectic content, such as 8006, that have useful combinations of strength and ductility at room temperature and retain their strength at elevated temperatures. These properties are due to the fine grain size stabilized by the finely dispersed iron-rich second phase. Alloys such as 8011 are based on Al–Fe–Si but with more than 1 wt% total alloying element present to give correspondingly higher strengths. Such alloys find application as foil and closures as well as heat exchanger finstock.

An Al–Ni–Fe alloy 8001 is used in nuclear power generation for applications demanding resistance to aqueous corrosion at elevated temperatures and pressures. Other alloys included in the 8xxx series are bearing alloys commonly used in cars and trucks which are based on the Al–Sn system (e.g., 8280 and 8081).

### 3.08.3.4 Properties of Aluminum Alloys

The basic physical properties of aluminum are given in Table 3.

The diverse and exacting technical demands made on aluminum alloys in different applications are met by the considerable range of alloys available for general and specific engineering purposes, each of which have been designed and tested to provide various combinations of useful properties. These include strength/weight ratio, corrosion resistance, workability, castability or high temperature properties, to mention a few. Some basic properties of these standard alloys are given in Table 4.

**Table 3** Properties of aluminum

<i>Physical</i>	
Atomic number	13
Atomic weight	10.0
Atomic volume	26.97
Valency	3
Crystal structure	Face-centered cubic
Interatomic distance	2.863 Å

Thermal conductivity at 273 K	$214 \text{ W m}^{-1} \text{ K}^{-1}$
<i>Electrical</i>	
Elec. vol. resistivity at 293 K	$2.7\text{--}3.0 \mu\Omega \cdot \text{cm}$
Elec. vol. conductivity at 293 K	63–57% IACS
Temp. coeff. of elec. resistance per K for 293 K	0.0041
Thermoelectric power vs. platinum	+0.41 mV/100 K

Wrought aluminum alloys are fabricated into the familiar semifabricated forms such as plates, sheets, extruded sections and drawn tubes from direct chill (DC) cast blocks or billets as appropriate. The largest DC cast rolling blocks are of the order of 20 tons, and most of these are made from primary metal alloyed and cast at smelters. These large rolling blocks are processed through a series of breakdown mills as well as hot and cold tandem mills to produce the wide range of plate and sheet products that represent the largest tonnage of aluminum alloy usage. Continuous casting (CC) of aluminum for sheet products has grown from its commercial inception in the early 1960s to more than 6 Mt per year capacity today. These CC alloys have both modified composition and microstructure when compared to their DC cast equivalents, and this results in modified corrosion behavior. Joining may be carried out by mechanical methods (such as riveting and bolting), brazing, soldering, adhesive bonding or welding. The argon-shielded arc welding methods (MIG and TIG), and more recently, friction stir welding are particularly appropriate where corrosion resistance of the welded joints is of importance.<sup>23</sup>

#### 3.08.3.4.1 Wrought aluminum alloys

The wrought aluminum alloys are often classified according to two major groups, which are the

non-heat-treatable, and heat-treatable wrought alloys. Non-heat-treatable alloys derive their strength from a combination of solid solution or dispersion hardening. Such alloys can be further strengthened by strain-hardening and cold work.

In contrast, the heat-treatable alloys are strengthened by solutionizing and subsequent age-hardening. The designations, properties and applications of wrought alloys are covered elsewhere in this chapter.

#### 3.08.3.4.2 Cast aluminum alloys

Naturally, casting alloys may not be worked or strain-hardened; however, they may be heat-treated. It was estimated that in 1997 ingots for casting represented a total of ~26% of the total aluminum market in the United States. Of this amount, about 60% was die cast, with the remainder either sand cast, permanent mold cast, etc. The strength of the cast component is typically lower than that of wrought alloys; however, a tensile strength of up to 485 MPa may be realized with heat-treated 2xx.x series casting alloys, with a number of commercial casting displaying a good medium strength in the vicinity of 300 MPa.

### 3.08.4 Processing of Aluminum Alloys

#### 3.08.4.1 Shape Casting

Cast products are usually produced in foundries from prealloyed metal supplied from secondary smelters,

although certain high-performance castings are made from primary metal. The three most commonly used processes are sand casting, permanent mold casting and die casting. Sand molds are gravity fed, whereas the metal molds used in permanent mold casting are either gravity fed or by using air or gas pressure to force the metal into the mold. In high pressure, diecastings, parts up to 5 kg are made by injecting molten aluminum alloy into a metal mold under substantial pressure using a hydraulic ram. Sand castings and permanent mold castings are made from alloys that respond to heat treatment; however, because of their entrapped gas content, die castings are not easily welded or heat treated. Approximately, 85% of aluminum alloy die castings are produced in aluminum-silicon-copper alloys. Permanent mold castings are used for higher production runs than diecastings and, as the metal mold produces rapid solidification, such castings have excellent mechanical properties, low porosity and good dimensional tolerances. Sand casting is a versatile and low-cost process used for a wide range of alloy types although such castings do not have dimensional accuracy and have a relatively poor surface finish. Plaster molds have better surface finish than sand castings, allowing castings to be made with fine detail and close tolerances. Investment casting uses refractory molds formed over expendable wax or thermoplastic patterns. The molten aluminum is then cast into the fired mold to produce precision parts with thin walls, good

dimensional tolerance and a fine surface finish that require little further machining.

Aluminum castings are found in most of the vehicles in use today from cars, buses and trains, to ships, aircraft and spacecraft. The wide variety of aluminum casting alloys available allows the selection of materials with good strength, good corrosion resistance and other special properties. Approximately, 60% of aluminum castings are used in transport applications, 15% in domestic and office equipment, 6% in general engineering applications and 5% in the building and construction industry. Aluminum castings form parts used in cooking pots, washing machines, refrigerators, chairs and tables, and in offices castings are used in furniture, computers and other small, lightweight, high-technology equipment.

However, despite their wide use comparatively, little work has been carried out to date to understand the corrosion behavior of aluminum casting alloys. Because of their high content of alloying elements such as silicon, iron and magnesium, casting alloys have a higher density of intermetallic particles when compared to wrought aluminum alloys. Processing parameters such as cooling rate and pouring temperature and even minor alloying element content variation lead to significant changes in the microstructure of these alloys.

#### 3.08.4.2 Direct Chill Casting

This is a semicontinuous process used for the production of rectangular ingots or slabs for rolling into plate, sheet and foil and cylindrical ingots or billets for extruded rods, bars, shapes, hollow sections, tube, wires and rods. Most of the production is from primary aluminum and process scrap or selected post-consumer scrap. The shallow mold for a DC casting is made from an aluminum- or copper-based alloy with good thermal conductivity, and the walls of the mold are water cooled. The base of the mold is lowered hydraulically or mechanically at a speed that depends on the size and composition of the alloy being cast.

Casting starts by pouring molten metal into the mold which solidifies on contact with the water-cooled base of the mold. Before the mold is filled, it is lowered and the pouring rate is controlled to maintain a constant level of metal in the mold. The solidified shell holding the molten metal is directly chilled by water sprays directed onto the emerging ingot, and pouring is continued until the required ingot length is cast. For small diameter ingots, multiple ingots in lengths of 3 to 4 m may be cast in one

drop. This requires a high degree of automation and control for both quality and safety.

Before DC casting, the melt is degassed, filtered and grain-refined. The cast surface is often uneven, and the outermost 20 cm of the cast surface is often of a coarser grain structure than the interior and can contain higher levels of segregates. The outer cast surface is commonly scalped off.

An ideal structure for a DC cast ingot is a fine and uniform grain size, and this is achieved by using a grain refining master alloy in rod form that is fed into the molten alloy during casting at a rate of  $0.2-1 \text{ kg t}^{-1}$  of alloy. Grain refiner is usually an alloy that contains 5% titanium and 1% boron as intermetallic phases of titanium aluminide and titanium diboride. These provide the nuclei for solidification in the cooled melt. Cast ingots have a 5–20-mm-thick coarse-grained shell zone with fine grain and a coarse-grained center. DC cast ingots also suffer from macrosegregation and the middle of the ingot can have a significantly different composition.

The stress in the cast ingot depends on the alloy composition, the size and shape of the ingot, the casting speed and the cooling rate, but can be large enough to result in ingot splitting. Certain high-strength 7xxx alloys require stress relieving by heating to 450 °C and slow cooling to prevent splitting.

Thermodynamic considerations often fail to predict correctly the phase content and solid solution content of the as-cast microstructure because of the nonequilibrium nature of solidification during DC casting. This is important, as alloy corrosion properties are controlled by solid solution levels and intermetallic phase crystallography and morphology, which depend on complex kinetic competitions for nucleation and growth. An understanding of the factors that govern phase selection in aluminum alloys under conditions of nonequilibrium solidification is important since varying solidification conditions can lead to variations in secondary Al–Fe and ternary Al–Fe–Si phase contents at different positions in the casting, which in turn can lead to a degradation in the corrosion resistance of the fabricated products.<sup>24</sup>

Following DC casting, ingots are homogenized at high temperature between 450 and 630 °C prior to rolling or extrusion. Homogenization reduces segregation, encourages the transformation of metastable secondary and ternary phases into equilibrium phases and acts to equilibrate solid solution levels of soluble elements, resulting in certain cases in the precipitation of dispersoids. Homogenization can

therefore exert a significant influence on corrosion performance. The transformation of Al-Fe phases to Al-Fe-Si phases, known as beta to alpha transition, is particularly important in the processing of 6xxx extrusion alloys and 3104 can stock.<sup>25</sup> These transitions can exert a controlling influence on subsequent corrosion behavior.

### 3.08.4.3 Hot and Cold Rolling

Rolling blocks or slabs that are up to 30 tons in weight are scalped by milling away the cast surface and usually have their tops and bottoms sawn off. Slabs are heated to a temperature in the range 400–500 °C and passed through a reversing breakdown mill using heavy reductions per pass to reduce the slab gauge down to 15–35 mm. The surface of the slab undergoes intense shear deformation during this process, and a thin deformed layer is developed that can have a major influence on the subsequent corrosion performance of the rolled sheet if the layer is not removed by chemical or electrochemical cleaning.<sup>26</sup> The slab from the breakdown mill is then hot-rolled on a multi-stand tandem mill down to a gauge of 2.5–8 mm. Strip is coiled from the hot mill in tandem. Hot rolling deforms the original cast structure and the as-cast grains are elongated in the rolling direction. Depending on the alloy composition, temperature and rolling reduction, recovery processes and partial recrystallization can take place during hot rolling and the slow cooling of the hot-rolled coil. The elongated microstructure developed during hot rolling can have a profound effect on corrosion properties such as stress-corrosion cracking and exfoliation corrosion. For example, the exfoliation corrosion of 7xxx alloys was shown to be due to manganese segregation during DC casting, which developed into a banded microstructure during hot rolling, and exfoliation corrosion occurred as a result of preferential matrix attack adjacent to bands of manganese-containing intermetallic phases.<sup>27</sup>

Cold rolling is usually carried out continuously on multiple-stand tandem mills in which each stand has four rolls and the small diameter work rolls are prevented from bending by large diameter backup rolls. Surface roughness is controlled by the surface finish of the steel rolls. In cold rolling, there is still asperity contact between the roll and the aluminum surface and this can also produce a deformed surface layer with lower corrosion resistance than the underlying alloy. Removal of this surface has been shown to be important for the control of filiform corrosion of coil-coated aluminum architectural sheet.

### 3.08.4.4 Extrusion

In aluminum extrusion, a hydraulic ram forces a preheated billet held in a fixed container against a die and squeezes the metal through the die opening. The billet surface sticks to the container wall and a new surface is generated on the extrudate. However, this is not the case in backward or indirect extrusion, where the billet surface becomes the surface of the extrusion. Control of temperature and speed is important to avoid problems associated with overheating. However, most of these problems relate to surface defects seen during finishing operations such as anodizing rather than to direct corrosion issues. As with rolling corrosion of extruded sections is controlled largely by the distribution of primary intermetallic phases from DC casting and how these phases are broken up and elongated in the extrusion direction. Grain size and shape are important particularly if recrystallization does not occur and the as-cast grain structure is elongated in the extrusion direction. Partial recrystallization of an outer band of the extrusion can lead to a duplex structure with a predominately fibrous core and a thin, recrystallized outer zone.

### 3.08.4.5 Continuous Casting

Aluminum flat products can also be produced by twin roll casting or twin belt casting. This effectively removes the requirement for DC casting, formal homogenization and hot rolling. Molten aluminum is directly cast onto a water-cooled hollow steel roll or onto a cooled belt or block. Growth in continuous casting capacity has increased to more than 6 Mt per year from almost zero in 1960. Continuous casting has proven to be remarkably effective for the production of coiled strip suitable for coil coating for use as painted architectural sheet and for foilstock.

From a corrosion perspective, as solidification is more rapid in continuous casting, higher levels of supersaturation are achieved and the size of iron-bearing intermetallic phases is refined. This can be beneficial from a corrosion perspective. However, the surface quality is generally inferior to more conventionally cast and rolled strip, as the cast surface is not removed by scalping and variations in casting conditions can lead to surface streaks that persist at the final gauge after cold rolling. The range of alloys that can be made by continuous casting is more limited, and to date, only limited success has been achieved with automotive sheet alloys although belt

casting capacity for this purpose has been installed in Japan.

Continuous casting is particularly suitable for making strip from secondary metal sources such as recycled post-consumer scrap. This, together with the lower surface quality, has raised concerns about corrosion resistance, but service experience of painted architectural sheet has been positive provided that the sheet is properly cleaned prior to pretreatment and coating.

### 3.08.5 Corrosion of Aluminum Alloys

Aluminum is a very reactive metal with high affinity for oxygen. This is indicated from its position on the electromotive force series. The metal is nevertheless highly resistant to most atmospheres and to a great variety of chemical agents. This resistance is due to the inert and protective character of the aluminum oxide film which forms on the metal surface and reforms rapidly if damaged. In most environments, therefore, the rate of corrosion of aluminum decreases rapidly with time.

The protective oxide film on aluminum attains a thickness of about 1 nm on freshly exposed metal in seconds. Oxide growth is modified by impurities and alloying additions and is accelerated by increasing temperature and humidity and immersion in water. The protective oxide film inhibits corrosion because it is both resistant to dissolution and a good insulator that prevents electrons produced by oxidation of the metal from reaching the oxide/solution interface, where either the cathodic reduction of oxygen or water can take place. Restricting these cathodic reactions reduces the amount of aluminum oxidation that can occur.

The oxidation of aluminum at room temperature is reported to conform to an inverse logarithmic equation for growth periods up to 5 years.<sup>28</sup> At elevated temperatures, oxidation studies over shorter periods illustrate conformity to parabolic, linear and logarithmic relationships according to time and temperature. These kinetic variations are attributed to different mechanisms of film formation.<sup>29,30</sup>

Corrosion of aluminum is an electrochemical process that involves the dissolution of metal atoms; so it can take place only once the protective oxide film has been dissolved or damaged. Aluminum is amphoteric in nature, meaning its oxide film is stable in neutral conditions but soluble in acidic and alkaline environments. The thermodynamic stability of aluminum's oxide film is expressed by the potential versus pH (Pourbaix) diagram shown in [Figure 3](#).<sup>31</sup>

This diagram indicates the theoretical circumstances in which aluminum should show corrosion (forming  $\text{Al}^{3+}$  at low pH values and  $\text{AlO}_2^-$  at high pH values), passivity due to hydrargillite, that is,  $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  (at near-neutral pH values) and immunity (at high negative potentials). The nature of the oxide actually varies according to temperature, and above about 75 °C boehmite ( $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ ) is the stable form. It should be noted that the potential versus pH diagram does not indicate one of the most important properties of aluminum, that is, its ability to become passive in strongly acidic solutions of high redox potential such as concentrated nitric acid.

#### 3.08.5.1 Forms and Causes of Corrosion

Corrosion is an electrochemical process, and hence the corrosion potential of different aluminum alloys is of considerable importance. In addition, the difference between the potential of aluminum alloys and other metals is important, as is the relationship between the potential of microstructural constituents of a single alloy. As we discuss in the following, the compositions of solid solutions and additional phases, in addition to the spatial distribution and number density of additional phases, impact both the extent and the morphology of resultant corrosion. The major forms and causes of corrosion are covered individually below.

##### 3.08.5.1.1 General dissolution

As a general rule, general dissolution occurs spontaneously in strongly acidic or strongly alkaline solutions (as predicted by the Pourbaix diagram), but there are specific exceptions. Thus, in concentrated nitric acid, the metal is passive and the kinetics of the process is controlled by ionic transport through the oxide film, while inhibitors such as silicates permit the use of some alkaline solutions (up to pH 11.5) to be used with aluminum. Even where corrosion may occur to a 'limited' extent, aluminum is often preferred to other metals because its corrosion products are colorless.

##### 3.08.5.1.2 Pitting and localized corrosion

This is the most commonly encountered form of aluminum corrosion. In certain near-neutral aqueous solutions, a pit once initiated will continue to propagate as the solution within the pit becomes acidified and the alumina is no longer able to form a protective film to prevent pit growth.<sup>32</sup>

Pitting arises from the creation of a very localized and 'aggressive' environment that breaks down the

**Figure 3** Pourbaix diagram for aluminum.

nominally passive and corrosion-resistant film on the metal. Such an environment usually contains halide ions, of which chlorides are the most common. Solutions containing chlorides are very harmful, while the presence of chlorides can create local corrosion potential 'drops' between the metal surface and the occluded region at which the chloride is concentrated or accumulated. Pits may form at scratches, mechanical defects or stochastic local discontinuities in the oxide film. Pitting occurs only in the near-neutral pH range since the oxide is unstable in a bulk sense under acidic or alkaline conditions. Chlorides facilitate the breakdown of the film by forming  $\text{AlCl}_3$ , which is also usually present in the solution in the pits. When aluminum ions migrate away from the pits, alumina precipitates as a membrane, further isolating and intensifying local acidity, and sustained pitting of the metal results.

With increasing purity of aluminum, greater resistance to pitting corrosion is developed. On high-purity materials, however, any pits that develop are likely to be deeper though fewer in number than those formed in more impure metal. In some special applications, notably in contact with ammonia solutions or pure water at elevated temperatures and pressures, the iron and silicon present in commercial-purity metal

are beneficial and retard corrosion. Up to about 5% magnesium improves the corrosion resistance to seawater.

While the shape of the pits can vary rather significantly depending on the alloy type and environment, pit cavities are nominally hemispherical. This distinguishes pits from other forms of corrosion such as intergranular or exfoliation corrosion. Pitting is strongly influenced by the alloy type and microstructure, and [Section 3.08.5.2](#) covers the effect of microstructure on the corrosion mode in more detail.

The pitting potential defines the conditions under which metals in the passive state are subject to corrosion by pitting, and also serves as a means of discriminating the pitting propensity of alloys. However, the pitting potential yields no information regarding the number and size of pits which may form upon a given alloy, but it does give a measure of the driving force required for pitting to proliferate for a given alloy. There is a definite pitting potential for aluminum and its alloys in near-neutral pH environments, which has been readily and reproducibly measured by many investigators.<sup>33–35</sup>

A review of certain aspects of pitting corrosion of aluminum was given by Smialowska.<sup>18,36</sup> This review highlighted that from a detailed mechanistic point of view, the processes (at the atomic level) that lead

to breakdown of the film due to halide interaction are presently not understood in sufficient detail. However, different analytical techniques including selected ion monitoring (SIM), X-ray photoelectron spectroscopy (XPS) and autoradiography have revealed a clear adsorption of  $\text{Cl}^-$  on passive films of aluminum.<sup>36</sup>

In addition, since the 1980s, the work of Macdonald and coworkers has endeavored to explain the role of the film structure on pitting using the point defect model.<sup>37–41</sup> This model hypothesizes that chloride ions may be incorporated into the passive film by occupying anion vacancies resulting in a decrease of anion vacancies and an increase in cation vacancies. Cation vacancies are then posited to pile up at the metal interface leading a film breakdown.

More recently, certain researchers have observed current oscillations at a constant anodic potential below the pitting potential for different aluminum alloys.<sup>42–45</sup> The occurrence of these oscillations was explained by the formation and repassivation of nano/micropits termed ‘metastable’ pits. These investigations have been largely carried out to understand the processes that lead to the formation of stable pits. A typical current versus time record is shown below in Figure 4.

Recent studies have shown that the surface of rolled, ground or machined aluminum alloys have deformed surface layers that range in thickness from 100 to 200 nm up to several microns<sup>46,47</sup> and that the presence of these layers has a strong effect on the initiation of pitting corrosion. These deformed layers are characterized by ultrafine grains formed as a result of the high levels of shear strain locally experienced by the aluminum alloy surface. The

**Figure 4** Current vs. time record for AA7075-T651 in deaerated 0.1 M NaCl held potentiostatically at  $-0.755 V_{\text{SCE}}$ . Courtesy of Mary K. Cavanaugh.

surface layer grains are 50–100 nm in diameter, are stabilized by oxide particles on their boundaries and are more susceptible to corrosion than the underlying bulk alloy. Deformed layers on AA3005 and similar architectural alloys are activated by the preferential precipitation of manganese-containing dispersoids, whereas the similar layers on AA6016 and AA6111 automotive AA7075 aerospace alloys are more susceptible to pitting due to the preferential precipitation of the aging precipitate. High-shear processing of the surface of aged alloys results in the dissolution of the aging precipitate and this can lead to double breakdown potentials in polarization tests, as the surface is effectively in an underaged state and the pits are at a lower potential than the underlying bulk alloy.<sup>48</sup>

### 3.08.5.1.3 Bimetallic or galvanic corrosion

Aluminum is anodic to many other metals, and when it is joined to them in a suitable electrolyte which may even be a damp, porous solid, the resultant potential difference (see Table 5) causes a current to flow and result in considerable corrosion. Corrosion is most severe when the resistance of the electrolyte is low, for example, seawater. In some cases, surface moisture on structures exposed to an aggressive atmosphere can give rise to galvanic corrosion.

**Table 5** Comparison of measured corrosion potentials according to ASTM G-69

Alloy/material	Corrosion potential ( $V_{\text{SCE}}$ )

8090-T7	−0.75

The corrosion potentials for a range of non-heat-treatable (wrought), heat-treatable (wrought), and cast aluminum alloys with some other standard corrosion potentials based on measurements made according to ASTM G 69 are shown in [Table 5](#).

In practice, copper, brasses and bronzes in marine conditions cause the most trouble. The danger from copper and its alloys is enhanced by the slight solubility of copper in many solutions and its subsequent redeposition on the aluminum to set up active local cells. This can occur even when the copper and aluminum are not originally in contact: for example, when water running over cuprous surfaces subsequently comes into contact with aluminum. Similarly, water washings from lead can cause pitting of aluminum. The controlling factor with lead and cuprous washings is the solvency of the water, so soft water is the most damaging in this respect. The successful utilization of these metals in close proximity to aluminum, for example, in plumbing and roofing, therefore requires careful design to avoid the transfer of a harmful solute to the aluminum.

Contact with steel, though less harmful, may accelerate attack on aluminum, but in some natural water and other special cases, aluminum can be protected at the expense of ferrous materials. Stainless steels may increase attack on aluminum, notably in seawater or marine atmosphere, but the high electrical resistance of the two surface oxide films minimizes bimetallic effects in less aggressive environments. Titanium appears to behave in a similar manner to steel. Aluminum–zinc alloys are used as sacrificial anodes for steel structures, usually with trace additions of tin, indium or mercury to enhance dissolution characteristics and to render the operating potential more electronegative. Aluminum–55% zinc alloys applied as hot dip coatings are also used extensively as a protective coating for steel for roofing and automotive applications.

Additions of elements such as zinc, tin, indium and mercury activate aluminum electrochemically and are 4 of the 10 elements that can enhance aluminum dissolution in aqueous electrolytes when contained as solute in the aluminum solid solution. The full list of these activators is antimony, zinc, lead, cadmium, thallium, bismuth, tin, indium, gallium and mercury in the order of increasingly negative potential. When these activators are mixed, the potential is controlled by the dominant activator which is the one with the highest melting point.<sup>49</sup> Aluminum alloys are similarly activated by additions of the activator elements to the electrolyte. These additions may be used to

turn aluminum into an anode plate for dry cells or metal–air batteries. The best addition for this purpose has been found to be tin together with an addition of magnesium. The magnesium addition is required to prevent a higher level of activation, and hydrogen production associated with the use of activators that can form hydrides.<sup>50</sup>

Aluminum in contact with galvanized steel may accelerate attack on the zinc coating and this is particularly noticeable when there is an unfavorable area ratio, as with galvanized fittings on aluminum sheets. In alkaline solutions, however, aluminum may be preferentially attacked. The copper-bearing aluminum alloys are nobler than most other aluminum alloys and this can accelerate galvanic attack on these, notably in seawater. Mercury and all the precious metals are harmful to aluminum.

Bimetallic corrosion of aluminum is a frequent cause of service-related corrosion failures, as the rate of attack can be rapid and corrosion can be severe and unexpected. In automotive applications, galvanic corrosion of aluminum is found in accelerated vehicle and component tests, particularly where aluminum is in direct electrical and electrolytic contact with a nobler metal. The solution is generally simple and involves providing sufficient protection using combinations of paints and barrier tapes to ensure that either electrical or electrolytic continuity is broken.

#### 3.08.5.1.4 Crevice corrosion

If a crevice is formed between two aluminum surfaces, or between the surfaces of aluminum and a nonmetallic material (i.e., a polymer) localized corrosion may occur within the crevice in the presence of electrolyte.

Crevice corrosion is due to the formation of a local cell, since at the mouth of the crevice (whether it is submerged or not) the concentration of oxygen is higher than that within the crevice. The difference in oxygen concentration leads to a difference in local corrosion potentials leading to corrosion in the ‘less noble’ area, which is the oxygen depleted zone. Concomitantly, the oxygen rich zone (i.e., the mouth) assumes the role of the cathode. This mode of attack is often termed ‘differential aeration cell corrosion’ or ‘concentration cell corrosion,’ which are terms that may be applied more generally to describe corrosion phenomena other than crevice corrosion.

Crevice corrosion can be a very problematic form of corrosion in an engineering sense, as the sites for crevice corrosion are often difficult to avoid in ‘real’ constructions which include welded lap joints,

rivetings, valve seats, or even deposits that arise in service.<sup>51</sup> Crevice geometry is the governing factor that determines the susceptibility, or conversely the resistance, to crevice corrosion. As a result, crevices are defined by their degree of tightness and their depth (distance from the mouth).

The general rules for the severity of crevice corrosion are presently under active research for several metal alloy systems, including aluminum.<sup>51–53</sup> Typically, in aluminum, tighter crevices lead to more rapid initiation of attack (owing to less electrolyte and a steeper oxygen concentration profile being achieved more rapidly). In addition, increasing crevice depth may also increase the likelihood of crevice initiation. Elimination of crevices should be done at the design stage where possible, and when unavoidable, they should be kept as open and shallow as possible or possibly even sealed with some type of appropriate non-crevice-forming sealant.

#### 3.08.5.1.5 Filiform corrosion

Filiform corrosion may be considered as a specific type of differential aeration cell corrosion that occurs from defects where the bare metal is exposed on painted or coated aluminum surfaces.<sup>2</sup> Filiform corrosion attack has a unique appearance that resembles fine filaments (worm-like threads) emanating from one or more defects in semirandom directions. Much like crevice corrosion, filiform attack is driven by a differential aeration cell with an anodic head growing under the coating and a cathodic tail where oxygen is reduced. The filiform filaments are filled with corrosion products that can include alumina gel and partially hydrated corrosion products. Typical filiform filament growth rates average about 100  $\mu\text{m}$  per day.<sup>2</sup> Filiform corrosion has been an issue for aluminum alloys in the aging aircraft sector. This is because aircraft are routinely painted for corrosion protection with polyurethanes and more complex coating systems.<sup>53–56</sup> Filiform corrosion, however, is not observed in cases where aluminum has been anodized or conversion-coated. More recently, filiform corrosion has also been observed in automobiles with aluminum closure sheet, in architectural sheet in Northern Europe and in packaging products.<sup>46,47</sup>

Recent work has shown that susceptibility to filiform corrosion in architectural and automotive applications in most if not all cases is due to the presence of a deformed layer on the surface of the sheet. For architectural applications, this is the residual surface layer from the high levels of surface shear induced by hot and cold rolling that becomes corrosion

susceptible as a result of the preferential precipitation of manganese-containing dispersoid particles. This type of deformed layer-induced filiform corrosion can be prevented by acid or alkaline etching to remove the deformed surface layer, by reducing the manganese level in the alloy or by heat treatment to precipitate the manganese from solid solution before rolling. In automotive applications, the susceptibility to filiform corrosion is induced by the grinding treatment that is used to rectify surface blemishes prior to painting. This type of corrosion is prevented by limiting the rectification grinding treatments in vehicle areas susceptible to stone chip damage in service or by providing additional protection to the painted surface to prevent stone chip damage.<sup>57</sup>

#### 3.08.5.2 Effects of Microstructure on Corrosion

The microstructure of aluminum alloys develop as a result of alloy composition, including impurities, casting practice and thermomechanical treatment. From the corrosion perspective, the dominant features of alloy microstructures are grain structure and the distribution of second phase (intermetallic) particles as constituent particles, dispersoids or precipitates. Such particles have electrochemical characteristics that differ from those of the surrounding alloy matrix, making the alloys susceptible to localized forms of galvanic attack, that has been termed microgalvanic corrosion.

Over the years, a number of studies have been carried out in order to assess the effect of specific intermetallic particles on the corrosion susceptibility of specific aluminum alloys.<sup>34,58–62</sup> In the mid-1990s, Buchheit collected the corrosion potential values for intermetallic phases common to aluminum alloy families mainly in chloride-containing solutions.<sup>18</sup> More recently, various groups have focused on the electrochemical properties of Fe-containing intermetallics<sup>63,64</sup> and Cu-containing intermetallics<sup>65–67</sup> and this has been expanded into a more comprehensive treatise covering a variety of common intermetallics present in commercial aluminum alloys (both wrought and cast).<sup>32</sup> A summary of the results of these studies is shown in Table 6.

The identification and structural characterization of intermetallic particles present in aluminum alloys have been quantified by particle extraction techniques combined with X-ray diffraction, by automated electron probe microanalysis and by scanning and transmission electron microscopy combined with X-ray microanalysis. For example, Buchheit *et al.*<sup>67</sup>

quantitatively determined the chemical composition of constituent particles in AA2024-T3 and were able to determine both their stoichiometry and relative surface area.

Intermetallic particles in aluminum alloys may be either anodic or cathodic relative to the matrix. As a

result, two main types of pit morphologies are typically observed.<sup>68,69</sup> The so-called circumferential pits appear as a ring of attack around a more or less intact particle or particle colony and the corrosion attack is mainly in the matrix phase. This type of morphology arises from localized galvanic attack of the more active matrix promoted by the more noble (cathodic) particle, as shown in **Figure 5**.

The second pit type of morphology is due to the selective dissolution of the constituent particle. Pits of this type are often deep and may have the remnants of the particle in them. This morphology has been interpreted as particle fallout, selective particle dissolution in the case of electrochemically active particles, or in the case of some Cu-bearing particles, particle dealloying and non-faradaic liberation of the Cu component.

Localized corrosion activity is, however, a complex phenomenon that is still under active research. Localized corrosion leads to local pH gradients, as recently studied by Scully *et al.*<sup>61</sup> Cathodic sites of enhanced oxygen reduction will naturally generate hydroxyl ions and promote local pH increases, which can then modify the subsequent rate and morphology of corrosion propagation. The precise morphology of particle-induced pitting is important for the emerging damage accumulation models. For these models to be predictive, it is necessary to develop a comprehensive,

**Table 6** Summary of corrosion potentials in NaCl at the given concentration for intermetallic particles common to Al alloys

self-consistent account for this type of pitting. In cases where the electrochemical characteristics of constituent particles have been rigorously characterized, they have been found to have much more complicated behavior than that could be categorized by simple characterizations such as 'noble' or 'active.'

Generally, the constituent intermetallics of interest for a particular aluminum are those that appear in the greatest proportion either by size or by frequency. Variations in thermal treatments will have marked effects on the local chemistry (hence local electrochemistry) and hence the local corrosion resistance of the alloy. Similarly, the impact of mechanical working will influence the number of grain boundaries (hence grain boundary precipitates) and the distribution and size of constituent type particles (which tend to break up and align in the direction of working). Furthermore, directional solidification and segregation from casting will influence the resultant microstructure, all of which will impact the type and number of particles that form and their location within the material.

### 3.08.5.3 Intergranular Forms of Corrosion

IGC is a phenomenon of which the precise mechanisms have been under debate for almost half a century.<sup>70–76</sup> While in a global sense we can consider IGC as a special form of microstructurally influenced corrosion, in a generic sense, IGC can be summarized as a process whereby the grain boundary region of the alloy is anodic to the bulk or adjacent alloy microstructure.

Corrosion is often microgalvanic (or even nanogalvanic), with activity developing as a result of some heterogeneity in the grain boundary structure. In aluminum–copper alloys, precipitation of  $\text{Al}_2\text{Cu}$  particles at the grain boundaries leaves the adjacent solid solution anodic and more prone to corrosion.<sup>76</sup> With aluminum–magnesium alloys, the opposite situation occurs, since the precipitated  $\text{Mg}_2\text{Al}_3$  phase is less noble than the solid solution. However, serious intergranular attack in these two alloys may be avoided, provided correct manufacturing and heat treatment conditions are observed.

In the case of the aluminum–magnesium system, almost all commercial alloys are supersaturated as the magnesium solubility at ambient temperatures is less than 1 wt%. This effectively means that for alloys with more than 3 wt% magnesium elevated service temperatures can lead to grain boundary precipitation and sensitization of grain boundaries to corrosion as intercrystalline attack. The extent of this

sensitization may be approximately deduced from the continuity of  $\text{Mg}_2\text{Al}_3$  precipitation at the boundaries as determined by optical metallography of polished and etched cross sections. Apparently, continuous or nearly continuous etched boundaries correspond to high levels of sensitization to IGC.

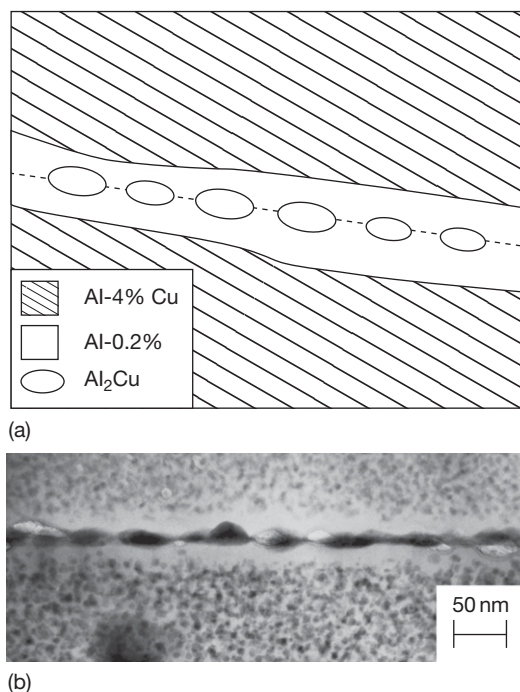

Although the precipitation of  $\text{Mg}_2\text{Al}_3$  may appear continuous from examination of polished and etched sections in an optical microscope, examination of microstructures at higher resolution in a scanning or transmission electron microscope invariably reveals the precipitation to be discontinuous. Susceptibility of AA5xxx alloys is controlled in practice either by limiting the level of magnesium in the alloy to below 3 wt%, as such alloys can be sensitized to IGC only under extreme conditions or by the use of a deliberate stabilization treatment for a more magnesium-rich alloy. Stabilization of AA5xxx alloys with more than 3% magnesium is achieved by a deliberate heat treatment to promote intragranular precipitation of  $\text{Mg}_2\text{Al}_3$ . The temperature and time of this treatment depend on the precise magnesium level in the alloy. In production sometimes, this process is carried out by a specific formal heat treatment, and sometimes the rolling practice is modified so that the required level of intragranular precipitation is achieved during warm rolling. The level of sensitization to IGC of a fabricated sheet, plate or extrusion can be easily determined by measurement of the NAMLT value. This is a 24 h exposure to nitric acid and a measurement of weight loss due to IGC and loss of grains. A NAMLT value of more than  $30 \text{ g cm}^{-2}$  of surface is necessary before an alloy has become sensitized to IGC or cracking.

In the case of Al–Zn–Mg alloys, where the precipitated phase is the highly anodic  $\text{MgZn}_2$  phase, IGC can occur rather readily. However, susceptibility to IGC is strongly dependent on the heat-treated condition and its effect on grain boundary solute segregation and the morphology and composition of the grain boundary precipitate and the surrounding alloy matrix.<sup>77</sup> The most resistant heat treatments are based on the use of overaging to the T7 condition. More complex heat treatments that involve retrogression and reaging are also used to provide a high level of IGC resistance with a lower loss of strength.<sup>1,2</sup>

The images in **Figure 6** help rationalize the origins of IGC.

IGC differs from pitting corrosion. While IGC may initiate from a pit, propagation of IGC proceeds more rapidly than pitting corrosion, and while both may have a deleterious effect on corrosion fatigue,

**Figure 6** (a) Schematic of hypothetical grain boundary in an Al-Cu alloy. This schematic indicates the different chemistry that exists in the grain interior, solute depleted zone (precipitate-free zone) and grain boundary precipitates – giving rise to electrochemical heterogeneity localized at the grain boundary region. (b) Conventional bright field TEM image of high-angle grain boundary in AA7022-T651, revealing grain boundary precipitates ( $\text{MgZn}_2$ ) and a distinguishable precipitate-free zone. Courtesy of Steven P. Knight.

IGC is more detrimental as the sharper corrosion front compared to a more rounded pit front is a higher stress concentrator that reduces the number of cycles to failure.

The test method used to evaluate susceptibility to IGC depends on the alloy type. For 5xxx series alloys, the NAMLT method (ASTM G 67) is adopted, whereas for 2xxx and 7xxx series alloys, ASTM G 110 is most common, employing testing in sodium chloride solutions containing hydrogen peroxide.

Exfoliation corrosion<sup>78</sup> of aluminum alloys is also frequently due to IGC. It generally occurs in cases where the alloy microstructure has been heavily deformed by rolling, extrusion or forging where the grain structure has been flattened and significantly extended in the direction of working. IGC attack from transverse edges and pits then runs along grain boundaries parallel to the alloy surface, and the resulting layers of corrosion attack are sometimes referred to as ‘layer corrosion.’ Exfoliation corrosion

is characterized by leafing off of layers of relatively uncorroded intragranular metal caused by the swelling of the corrosion product in the layers of IGC. Exfoliation corrosion is observed on aircraft components, for example, around riveted or bolted components or wing brackets. Testing for exfoliation corrosion is carried out by a number of ASTM tests, including the acidified salt spray test (ASTM G 85), the ASSET immersion test (ASTM G 66) and the EXCO immersion test (ASTM G 34).

### 3.08.5.4 Environmentally Assisted Cracking

Environmentally assisted cracking is a generic term that includes stress corrosion cracking (SCC), liquid metal embrittlement (LME), corrosion fatigue (CF) and hydrogen embrittlement (HE).

#### 3.08.5.4.1 Stress-corrosion cracking

Stress-corrosion cracking is a time-dependent, predominantly intergranular fracture mode in aluminum alloys that requires the simultaneous presence of a susceptible alloy, a sustained tensile stress and a corrosive environment.

The minimum tensile stress required to cause SCC in susceptible alloys is usually small and significantly less than the macroscopic yield stress.<sup>79,80</sup> Susceptibility to SCC has restricted the use of aluminum alloys, particularly the weldable 7xxx series alloys, to well-controlled and well-protected applications. There are several theories postulated for the mechanism of SCC. The main theories are either corrosion dominated where cracking is due to preferential corrosion along the grain boundaries by anodic dissolution (i.e., analogous to IGC) or hydrogen dominated where cracking along grain boundaries is enhanced by absorbed atomic hydrogen. The origin of this hydrogen is from IGC itself, and it is considered that the presence of absorbed hydrogen weakens grain boundaries.

While SCC is a very important corrosion-related phenomenon for aluminum alloys, in order to do justice to the topic, the reader is referred to specific monographs on the topic for a more detailed treatise of the SCC theories.<sup>81,82</sup> As previously mentioned, SCC in aluminum alloys is predominately intergranular, and this is seen in **Figure 7**.

Whether or not SCC develops will depend on both the duration and magnitude of the applied tensile stress. Fracture mechanics tools for the determination of crack growth rates are commonly used in the evaluation of SCC resistance for aluminum

**Figure 7** High-resolution SEM micrograph of an SCC fracture surface taken from an AA7079-T651 DCB specimen exposed to 75% relative humidity (specimen was from the T/6 position from a 3-in.-thick rolled plate). Courtesy of Steven P. Knight.

alloys. Such tests suggest a minimum (threshold) stress intensity is required for cracks to develop. This empirical test is largely the basis on which susceptibility to SCC is compared between different alloys under the specific conditions of a particular test or environment.<sup>2</sup>

Residual stresses in aluminum products that may arise as a result of quenching following solution heat treatment and cold working may play an important role in SCC should the level of residual stress be significant. After solution heat treating and quenching of aluminum aerospace and defense plates, it is a common practice to ‘stress relieve’ the cold-rolled plate by controlled plastic deformation typically to 1.5% by tensile stretching using a plate stretcher. The stress-relieved temper is designated by the Tx5x designation following the temper designation: examples include AA7075-T651 or AA2124-T351.<sup>1</sup>

SCC of 7xxx alloys occurs in water and water vapor in addition to chloride-containing electrolytes. Most other susceptible alloys fail only because of exposure to environments containing chloride ions.

Grain structure has a major influence on SCC of thick section aluminum wrought products. Generally, these products, of which plate is the main example, are not recrystallized and have directional, highly anisotropic grain structures. This means that cracks can

grow only in directions parallel to the rolling direction along the flattened grain boundaries. This means that testing the plate in the short transverse direction determines the lowest SCC resistance, followed by the long transverse, and then the longitudinal direction where the intergranular crack path is the most tortuous. This is a very important consideration for the use of plates in the aerospace and defense sector, where thin sections need to be designed such that there is little or no stress in the short transverse direction, or that the most SCC-resistant tempers are used. For welded aluminum alloys in defense applications, exposed short transverse edges are protected by buttering with weld metal or by the use of flame-sprayed protective coatings of sacrificial alloys based on aluminum zinc alloys.

Generally speaking, the low-strength and relatively pure aluminum alloys are not susceptible to SCC. The alloys most prone to SCC are the 7xxx, 2xxx and the higher strength 5xxx series alloys. Most service failures involving SCC have occurred as a result of residual stresses acting in the short transverse direction.<sup>83</sup> The relative resistance of certain aluminum alloys to SCC is tabulated in [Table 7](#) (adapted from Davies).<sup>2</sup> As noted, progressively overaging beyond the peak (T6) condition generally improves SCC resistance (while lowering strength).

### 3.08.5.4.2 Liquid metal embrittlement

While LME is not commonly observed in the routine use of aluminum alloys, it can be defined as a mode of attack that results in a complete loss of alloy ductility of a solid metal, below the normal yield stress, as a result of the surface being wetted by a liquid metal. LME-induced fractures may be both intergranular and transgranular but are generally intergranular in aluminum alloys. A micrograph of intergranular fracture due to LME in mercury is shown in [Figure 8](#).

It is well known that gallium in contact with aluminum can result in the disintegration of aluminum (or aluminum alloy) into individual grains. In addition, mercury can also embrittle aluminum and

**Table 7** Qualitative SCC resistance of aluminum alloys (in the rolled plate form)

Alloy and temper	SCC resistance
2014-T3	Poor

its alloys, though to a lesser extent. Aluminum has also been noted as being embrittled appreciably by tin–zinc and lead–tin alloys, indium and sodium.

### 3.08.5.4.3 Corrosion fatigue

Corrosion fatigue is the interaction of irreversible cyclic plastic deformation with localized corrosion (electrochemical) activity. The combination of each of the mechanisms, as well as the transition from initiation to propagation, is an issue under research currently and of considerable technological importance. However, corrosion pits have been observed to nucleate crack growth in structures subject to fatigue loading.<sup>84</sup>

Recent work has emphasized that in a fatigue study of aluminum alloy 7075-T6 all specimens in that study fractured from cracks associated with pitting.<sup>85</sup> Indeed, the numerous studies referenced with [Ref. 2](#) support the notion that pitting has a critical and detrimental effect on fatigue life.

Corrosion fatigue is an area that is of relevance to the aerospace sector and, indeed, a significant amount of work exists in the area, including several technical publications, dedicated monographs and handbooks.<sup>86,87</sup>

A fatigue crack can initiate from a corrosion pit or surface flaw when the flaw reaches a critical size at which the stress intensity factor reaches a threshold for fatigue cracking, or conversely when the rate of fatigue crack growth exceeds that of pit growth.<sup>88,89</sup>

A simple expression revealing the relationship between the critical pit size and the stress concentration can be given by:<sup>90</sup>

$$a_{p-c} = \pi \left( \frac{\Delta K_{th}}{2.2 K_t \Delta \sigma} \right)^2$$

where  $a_{p-c}$  is the pit–crack transition size and  $K_t$  is the stress concentration factor.

As noted in recent works,<sup>91</sup> aerostructures nominally experience corrosion between flights and fatigue loading during flight, suggesting the notion of ‘prior corrosion.’ This eludes to corrosion pits as precursors to fatigue cracking, a notion that can be seen elegantly in [Figure 9](#) as adapted from Harlow.<sup>92</sup>

Corrosion fatigue phenomena are diverse and specific to the environment and particular application at hand; however, certain variables that can influence corrosion fatigue crack growth propagation naturally include stress intensity, frequency of loading, stress ratio, alloy composition and microstructure (hence electrochemical potential) and the environment composition (and temperature).

**Figure 9** Schematic diagram of the development of corrosion and corrosion fatigue crack growth, indicating the transition from one mode to another via some threshold pit depth.

#### 3.08.5.4.4 Hydrogen embrittlement

Hydrogen is capable of dissolving in aluminum and its alloys both in the molten state and during thermal treatments at temperatures close to the alloy melting temperature where the atmosphere may include water vapor or excessive hydrocarbons. Hydrogen from molten aluminum results in porosity in cast products but does not have an influence on corrosion performance or hydrogen embrittlement.

However, there is experimental evidence that hydrogen generated during corrosion can penetrate into the grain boundaries and lead to embrittlement, a factor in the initiation and propagation of cracking (in particular SCC).<sup>93–96</sup> The mechanism by which hydrogen causes the embrittlement is difficult to study and is posited to act by either facilitating enhanced dislocation emission ahead of an advancing crack or by bond weakening and enhanced plasticity ahead of an advancing crack. The strongest evidence for the involvement of hydrogen in the SCC of 5xxx and 7xxx aluminum alloys comes from the observations of recovery and hydrogen evolution, from the measurement of sufficiently rapid grain boundary hydrogen diffusion and the precise matching of intergranular fracture surfaces that are striated with crack arrest markings.

Understanding hydrogen embrittlement is important in unraveling the mechanism and modes of failure processes including SCC; however, this far it has not been a key factor that has restricted the usage of high-strength aluminum alloys. There are no specific and generally accepted tests for assessing hydrogen embrittlement susceptibility of aluminum alloys, as

embrittlement in hydrogen gas has not been observed irrespective of the test pressure.

### 3.08.5.5 Influence of Environment and Processing

#### 3.08.5.5.1 Influence of alloy processing

The bulk microstructure of aluminum alloys is determined by the complex interaction between the cast microstructure and any subsequent thermomechanical processing operation. The situation is then complicated by any forming, finishing or joining operations that may locally modify alloy microstructures. Any deformation or heat-treatment processes that modify the local or bulk microstructure of the alloy will have an attendant influence on alloy corrosion. This is mainly due to the modification of the size and distribution of intermetallic phases at the micron, sub-micron and nanoscale and the change in grain size and grain shape from the cast state.

Soldered or brazed joints will usually have lower corrosion resistance than the parent metal, but sound-welded joints with resistance to attack equal to that of the parent metal can be obtained in most alloys.<sup>97</sup> Many assemblies contain angles, pockets or crevices that attract moisture originating either from external sources or from condensation. The corrosion so caused could often be avoided by redesign of the assembly, the provision of drain holes if possible (of at least 5 mm diameter) and the avoidance of horizontal surfaces being among the more important features.

#### 3.08.5.5.2 Atmospheric corrosion

The aluminum alloys as a group present with a pleasant gray color outdoors, which may deepen to black in industrial atmospheres. Superficial pitting occurs initially but gradually ceases, being least marked on high-purity aluminum. With some alloys, including the copper-bearing alloys and the medium-strength Al–Zn–Mg alloys, additional protection, for example, painting, is desirable in the more aggressive atmospheres to avoid any risk of IGC.

Gases such as hydrogen sulfide and carbon dioxide do not typically increase the corrosivity of the atmosphere towards aluminum.<sup>98</sup> Service experience extends over 100 years and includes such well known examples as Eros, which is in an excellent condition although cast in a low purity (98%) aluminum, and the cupola of San Gioacchino (St. James), a church in Rome that was covered in 1897 with a sheet 1.25 mm thick and now shows attack to a depth of less than 0.13 mm. Twenty-year tests at selected marine,

industrial and rural sites in the United States<sup>99</sup> have shown that the greater part of the attack takes place in the first or second year and that thereafter the rate of attack maintains a low value.

The relatively high percentage strength losses are due to the extremely thin test specimens. After 20 years, the average measured depth of attack for an aluminum–copper alloy at a sea coast test site did not exceed 0.15 mm. The falling-off in the rate of pitting with time is in sharp contrast to the behavior of the older established structural metals that have a fairly uniform corrosion rate throughout their life, and indicates that the relative merit of aluminum increases with scheduled life.

Aggressive environments include marine conditions and particularly industrial atmospheres containing high concentrations of acid gases such as sulfur dioxide; rain washing is beneficial in both environments, while dampness and condensation alone can accentuate the rate of attack in the presence of chlorides and acidic sulfates. The relative severity of industrial, marine and rural conditions has been demonstrated by the results of 7-year tests in the United States and the United Kingdom,<sup>100</sup> and in this work the benefit from rain washing was especially manifest for the industrial sites in the United Kingdom. While the continual removal of atmospheric pollution by rain washing is beneficial, the removal of the protective corrosion product is obviously undesirable. The retention of the weathered surface is therefore usually preferred unless aesthetic considerations are of major importance, in which case abrasive or specialist chemical cleaning are effective.

Over many years Alcan used the CLIMAT test originally developed by Bell Laboratories<sup>101</sup> to “classify industrial and marine atmospheres.” The test that has been standardized<sup>102</sup> involves the exposure of wire-on-bolt samples to the atmosphere of interest for a period of 90 days. Following the exposure, the wire-on-bolt samples are disassembled, cleaned and weighed, and the CLIMAT indices are determined from the percentage weight losses. Generally, three wire-on-bolt samples are exposed with aluminum wires wound on to plastic, copper and mild steel bolts. The relative values of the weight loss indexes enable the corrosivity of different sites to be compared and ranked. By 1988, it was estimated that Alcan had carried out over 13 000 individual CLIMAT tests in locations all over the world, and summarized versions of the test results have been published.<sup>103–105</sup> More recently, the CLIMAT test has been used to monitor and compare the severity of outdoor exposure sites in

Europe and to assess the corrosivity of the automotive environment. The test has also begun to be used to compare the severity of different types of cabinet tests compared to outdoor exposure sites.

In urban areas, atmospheric fallout of carbon from partially burned fuel can cause severe localized pitting by galvanic action, although this is not commonly encountered. Indoors, aluminum retains its appearance well, and even after prolonged use may show no more than slight dulling, or on aluminum–magnesium alloys a slight bloom. This superficial deterioration can be accelerated by the presence of moist conditions and condensation which in extreme cases may lead to staining.

In order to enhance the durability of structural aluminum, anodizing provides a good level of protection. Anodized aluminum extrusions can survive even prolonged exposure in accelerated salt spray testing, indicating that the anodizing process where applicable is an industrially acceptable means of protection.

#### 3.08.5.5.3 *Natural waters*

Immersed aluminum and its alloys have excellent resistance to attack by distilled or pure condensate water, and are used in industry in condensing equipment and in containers for both distilled and deionized water, as well as in steam-heating systems.<sup>106</sup>

Of the commercial alloys, only those that contain copper as a major alloying element are likely to corrode in unpolluted seawater, but pollution of the seawater may cause localized pitting attack to occur on other aluminum alloys. The Al–Mg alloys containing up to about 4.5% magnesium offer particularly good combinations of corrosion resistance and strength. Fouling collects readily on aluminum alloys, as on other materials, and where it may be necessary to use paints containing cuprous oxide for antifouling purposes, the risk of bimetallic corrosion must be substantially inhibited by a chemical pretreatment. Nowadays, the use of chromate priming paint in addition to mercury-containing antifouling compositions is not considered as a best practice. The behavior of aluminum in natural fresh water and tap water may vary, as these types of water differ widely in their dissolved solid content. No corrosion occurs immediately on immersion of aluminum and its alloys in these kinds of near-neutral water, and aluminum gives satisfactory service with all types of tap water provided regular cleaning and drying takes place, as occurs with aluminum hollowware. In some types of water, black or brown stains, which are largely due to

optical effects associated with the oxide film on the metal surface, occur. Although somewhat unsightly, the film is quite harmless and can be removed by simple methods such as boiling of fruits (e.g., rhubarb). Alternatively, preliminary boiling with pure water provides some protection against the staining, but can hardly be considered justifiable in most of the cases.

The combination of carbonate, chloride and copper is more damaging than if they are present singly or if one of them is absent,<sup>107,108</sup> so that some kinds of supply water are naturally more aggressive than others. The role of copper is of particular relevance, since as little as 0.02 ppm can initiate pitting in hard waters,<sup>109</sup> although more is required in soft waters which are otherwise less aggressive. In this context, however, it must be remembered that soft waters are inherently more cupro-solvent than hard waters; consequently, the conjoint use of aluminum and copper fittings is rarely advisable irrespective of the necessity for avoiding galvanic interaction when the two metals are in direct contact. This latter point has traditionally stifled the usage of aluminum in more routine plumbing applications, although use of aluminum in such applications is likely to be considered again as the price of brass- and copper-based fittings and pipework increases relative to the price of aluminum.

Once pitting has started, it may continue in solutions which would themselves be incapable of initiating corrosion. In water of all types, the rate of increase in the depth of pitting falls off rapidly with time. Water movement (of the order of  $0.3 \text{ m s}^{-1}$  or more) will reduce pitting or prevent its initiation. A rise in temperature tends to lead to higher corrosion rates at existing pits, but even with the most aggressive hard waters, above about  $50^\circ\text{C}$  the oxide-forming mechanisms act to prevent the initiation of pitting as shown by the long and satisfactory service given by aluminum hollowware, which is assisted in some waters by scale formation.

Where aluminum is to be used in direct contact with cold, natural water with no possibility of regular cleaning, clad aluminum alloys are the preferred materials. Aluminum–zinc alloys are used for cladding that is anodic to the core alloy and corrosion is therefore restricted to the surface cladding, thereby obviating the risk of perforation. Cladding with super-purity aluminum is preferable where it is important to have the minimal degree of total corrosion, but in this case, the potential relationship with the core is more critical and in some circumstances the cladding can actually become cathodic. Sacrificial protection may also be obtained from sprayed

coatings of appropriate composition which can be applied to extrusions and castings as well as to sheets, rods, plates and tubes. In practice, unclad aluminum–manganese alloys have been used for piping soft water in the United Kingdom and, more widely, in the United States.

#### **3.08.5.5.4 Underground corrosion by soils**

This is largely related to the presence of moisture which can leach out soluble constituents from the soil. As it is the case with natural water, the nature of the corrosive environment is a more important factor than the alloy used, provided that copper-bearing alloys are avoided. At present, it is difficult to produce a satisfactory classification of soils with respect to their aggressive action on aluminum alloys. Made-up ground, particularly when it includes carbonaceous cinders, is usually extremely corrosive, while neutral clays are often the least corrosive. It is desirable that protection should be given to all aluminum materials buried in soils<sup>110</sup> except where there is previous experience of satisfactory service from aluminum in a given soil. Pipe wrappings based on bitumen (or the now legislated-against chromates) are effective, while for cable sheathing, a continuous plastic coating provides both electrical and corrosion protection. Cathodic protection has been utilized for pipelines<sup>111</sup> but is not widely practiced; close control is necessary since overprotection can result in alkali attack (from excessive accumulation of hydroxyl ions generated from the CP). Potentials in the region of  $-1.0 \text{ V}$  versus saturated  $\text{Cu}/\text{CuSO}_4$  are favored although some divergence of opinion exists in this respect.

#### **3.08.5.5.5 Corrosion in chemical environments**

Detailed information about the behavior of specific chemicals is given in several works of reference.<sup>112–115</sup>

##### **Acids**

Most acids are corrosive to aluminum-based materials. The oxidizing action of nitric acid at concentrations above about 80%, however, causes passivation of aluminum. Very dilute and concentrated sulfuric acid dissolves aluminum only slowly. This is seen graphically in **Figure 10**.

Boric acid also exerts little attack on aluminum, while a mixture of chromic and phosphoric acids can be used for the quantitative removal of corrosion products from aluminum without attacking the metal.

Organic acids usually have low rates of attack on aluminum, notable exceptions to this generalization

**Figure 10** Action of nitric acid of various concentrations on commercial-purity aluminum at 20 °C. Adapted from *Aluminium in the Chemical and Food Industries*; British Aluminium: London, 1959.

being formic acid, oxalic acid and some chloride-containing acids such as trichloroacetic acid. Glacial acetic acid (pH 3) has no significant corrosive effect on aluminum but the rate of attack increases rapidly with decreasing concentration or in the absence of the traces of water normally present. The rate of corrosion in an acid solution rises rapidly with temperature, often doubling or more with a 10 °C rise.

A summary of the effect of dilute inorganic acids on the corrosion of aluminum is seen in [Figure 11](#).

### Alkalies

Alkalies are generally corrosive to aluminum; caustic soda is in fact used for chemical milling of aluminum. Ninety-nine percent pure aluminum is, however, resistant to ammonium hydroxide, even at pH 13, while the action of more dilute caustic alkalis can be inhibited by the use of silicates. Mild alkalis such as sodium carbonate are moderately corrosive and are not recommended for washing aluminum hollowware. Synthetic detergents, in general, give satisfactory service in cleaning aluminum, but those containing uninhibited sodium carbonate may give some surface roughening. Inhibitors such as silicates can prevent attack by the more dilute solutions.

Alloys of aluminum with magnesium or magnesium and silicon are generally more resistant than other alloys to alkaline media. The corrosion rate in potassium and sodium hydroxide solutions decreases with increasing purity of the metal, but with ammonium hydroxide the reverse occurs.

**Figure 11** Action of dilute (0.1 N) solutions of inorganic acids on commercial-purity aluminum at 25 °C. Adapted from *Aluminium in the Chemical and Food Industries*; British Aluminium: London, 1959.

### Inorganic salts

Most simple inorganic salt solutions cause virtually no attack on aluminum-based alloys unless they possess the qualities required for pitting corrosion, which have been considered previously, or hydrolyze in solution to give acid or alkaline reactions, as do, for example, aluminum, ferric and zinc chlorides. With salts of heavy metals, notably copper, silver and gold, the heavy metal deposits on the aluminum, where it subsequently causes serious bimetallic corrosion.

Some salts, notably chromates, dichromates, silicates, borates and cinnamates, have marked inhibitive power and are very effective in closed-circuit water systems. Care must be taken to ensure that a sufficient quantity of such anodic inhibitors as chromates is added, as otherwise attack, though occurring at fewer points, may be more severe at these points. Chromates and dichromates have little inhibitive power in strongly acidic solutions. It is emphasized that while chromates are mentioned herein for historical purpose, the toxicity of chromates has resulted in a dramatic decrease in their use in the past decade, and may result in a zero-usage policy on the global scene within the coming few years.

Aluminum is used in hydrogen peroxide processing and storage equipment partly because of its high corrosion resistance and also because it does not cause degradation of the peroxide.

**Organic compounds**

With many organic compounds, aluminum shows high corrosion resistance either in the presence or absence of water. The lower alcohols and phenols are corrosive when they are completely anhydrous, although this is rarely encountered in practice since repair of breaks in the natural protective oxide film on aluminum cannot take place in the absence of water. Amines generally cause little attack unless very alkaline.

Processing and storage equipment for many chemicals, including acetaldehyde, formaldehyde, nylon salt, methyl methacrylate, carbon tetrachloride, glycerol, triacetin, propionic acid, acetic acid and acetic anhydride, is manufactured from aluminum alloys, primarily because of their excellent corrosion resistance.

Aluminum has good resistance to petroleum products, and an Al–2Mg alloy is used for tank heating coils in crude-oil carriers. Caked-on deposits must be removed from the coils by hot seawater cleaning in order to maintain effective heat transfer and prevent corrosion. Aluminum is also used in the petroleum industry for sheathing for towers, heat exchangers, transport and storage tanks and scrubbers. Many industries use aluminum alloys for heat exchangers, clad alloys being used where pitting corrosion is liable to be initiated by one of the contacting materials. Heat exchangers in the gas industry have utilized duplex tubes, with aluminum on the water side and steel on the gas side in cases where aluminum is unsuitable owing to the presence of catechol which can attack it.

Aluminum does not become brittle at low temperatures and for this reason (and because of its corrosion resistance), it has been adopted for the carriage and storage of liquefied methane.

**3.08.5.5.6 High temperature corrosion****Dry atmospheres**

When exposed to high temperatures in dry atmospheres, aluminum is highly resistant to corrosion by most of the common gases, other than the halogens or their compounds.

**High temperature aqueous systems**

When aluminum corrodes at temperatures below 90 °C in aqueous systems, attack is usually by pitting. At temperatures between 90 and 250 °C (for the attainment of which considerable pressures are needed), uniform attack is the commonest form of aqueous corrosion. Above about 250 °C, uniform attack is merely the prelude to highly destructive

intergranular attack. The corrosion products from the uniform attack form a film which includes a barrier layer and a bulk film analogous to those formed during anodizing; it is the bulk film that controls the corrosion rate, which is not significantly affected by most common dissolved ions. The onset of intergranular attack occurs at about the same time as the crystallization of the amorphous barrier layer oxide. Kinetic studies indicate that over the temperature range from 100 to 363 °C the oxidation rate law is successively inverse logarithmic, parabolic and linear.<sup>116</sup>

The requirements of nuclear energy application fostered an interest in special alloys for service in high temperature aqueous environments, but their utilization has not been widespread. Encouraging results have been reported for alloys of 2Ni–0.5Fe and 1.2Ni–1.8Fe.<sup>117</sup>

Steam forms a protective white film at temperatures up to about 250 °C, but above this temperature steam can, under some conditions, react with aluminum progressively to form aluminum oxide and hydrogen. Sintered aluminum powder (SAP) has relatively good resistance to steam at 200 °C, but at about 300 °C an addition of 1% nickel to the SAP is needed to prevent rapid disintegration.

**Molten salts and metals**

Aluminum alloys resist the action of many molten salts which are nearly neutral in reaction. Molten sodium nitrate or mixtures of sodium nitrate and potassium nitrate are, even nowadays, most commonly used for salt-bath heat treatment of most aluminum alloys.

Molten metals generally attack aluminum alloys. Both zinc and tin form alloys by dissolution of aluminum, although the aluminum does not melt. Molten lead is inert to aluminum, and molten lead baths can be used for heating aluminum alloys.

**3.08.5.5.7 Aluminum in contact with other materials**

The aluminum alloys recommended for structural and architectural purposes (not including the high-strength alloys containing copper) have relatively good resistance to concretes, mortars, plasters and cement products. When freshly mixed, some of the materials release traces of alkaline products that are sufficient to stain aluminum (that is, to etch it). As soon as the mixture is set, the attack, however, is noted to cease, and even after many years' service attack on embedded aluminum is found – empirically – to be negligible.<sup>118</sup>

With cement and concrete under continuous wet conditions, there may, however, be surface attack. This decreases with time, and the strength of components is not significantly affected. Under embedment conditions, bituminous protection is advisable to avoid risk of cracking of the concrete due to stresses set up by the bulk of the voluminous aluminum corrosion product. Plasters are generally less aggressive than Portland cement. In damp environments, some corrosion of aluminum may arise in contact with the more open-grained building stones and brickwork, but the hard stones, such as granite, are inert. With building stone and brickwork, as with soils, it is the nature of the products that can be leached out which will determine whether aluminum corrodes. Unprotected aluminum, in the form of nails for example, can be satisfactorily used in contact with precast concrete blocks, which are usually noncorrosive to aluminum. Magnesium oxychloride compositions (used for flooring), on the other hand, stimulate corrosion of aluminum under moist conditions, as well as many insulation materials based on magnesium and calcium silicates.

Plastics generally do not react with aluminum and are widely used to provide insulation between other metals and aluminum. Rubber has no effect upon aluminum unless it is filled with carbon.

A few acid woods, such as oak, chestnut and Western red cedar, accelerate surface weathering of aluminum, but do not usually give rise to serious attack.<sup>119</sup> Timber preservatives containing soluble copper compounds should be avoided; creosote and zinc naphthenate are satisfactory preservatives for wood in contact with aluminum.

Common packaging materials are a potential source of aggressive substances,<sup>120,121</sup> and careful selection is recommended to avoid surface deterioration. Where paper is in contact with aluminum, the chloride content should be below 0.05%, sulfate content below 0.25% and copper content below 0.01%, and the pH of aqueous extracts in the range pH 5.5–7.5, in order to avoid corrosion in damp conditions. Papers and felts used in building applications should also conform to this specification as a minimum requirement and be of the highest quality, since metallic copper found in materials of inferior origin can result in severe local galvanic attack of aluminum. Tarpaulins are sometimes treated with copper-containing preservatives, and water leached from these has been found to cause corrosion of underlying aluminum sheets.

Fiberglass insulation produced from soda glass can cause pitting in conditions where leaching of

alkali occurs, for example, by condensation: the use of fiberglass produced from Pyrex glass is therefore preferred. Common putties of whiting/linseed oil composition do not attack aluminum; adhesion is obtained by allowing the metal surface to weather, or by applying an etch primer treatment to the metal. Both thermosetting adhesives (e.g., the phenolic types) and thermoplastic adhesives (such as paraffin and microcrystalline waxes or bitumen) are noncorrosive to aluminum. In general, adhesives applied to aluminum should not contain chlorides in excess of 0.05% (as NaCl) of the solid content, and should be free from copper- or mercury-containing fungicides. The presence in the adhesive of borax or sodium silicate is beneficial when one of the adhesive components is of an acidic character.

#### 3.08.5.5.8 Applied stress

Stress below the proof stress does not normally affect corrosion rates. Cyclic stresses in combination with a corrosive environment (corrosion fatigue) can produce failure at below the ordinary fatigue limit. Alloys susceptible to intergranular attack may corrode faster when stressed (see [Section 3.08.5.4](#)).

### 3.08.6 Corrosion Prevention Strategies

#### 3.08.6.1 Inhibitors

Corrosion of aluminum and aluminum alloys can be controlled by use of inhibitors added to aggressive aqueous environments. For the purpose of this discussion, an inhibitor is a chemical substance, soluble in water, that slows the corrosion cell process on aluminum. The range of inhibitors that slow corrosion of aluminum is large, and there are a number of useful ways to deliver chemical inhibitors when corrosion is a risk.

Soluble corrosion inhibitors act by slowing either the anodic reaction or the cathodic reaction or both. This gives rise to a useful scheme for classifying chemical inhibitors. Those that slow the anodic reaction are referred to as ‘anodic’ inhibitors, those that slow the cathodic reaction are ‘cathodic’ inhibitors, and those that slow both reactions are ‘mixed’ inhibitors.

For aluminum alloys, anodic inhibitors typically act to increase the pitting potential in electrochemical testing, or slow or suppress the onset of pitting in exposure testing. Even with good anodic inhibitors, pitting may occasionally occur if pre-existing defects

on the alloy surface are weak enough. Additionally, anodic inhibitors may have no effect on slowing the growth of existing pits.
